About the Authors

Tomislav Piasevoli is a Business Intelligence (BI) specialist with years of experience working with Microsoft SQL Server Analysis Services (SSAS). He successfully implemented many still-in-use BI solutions, helped numerous people on MSDN forum, achieved the highest certification for SQL Server Analysis Services (SSAS Maestro), and shared his expertise in form of MDX cookbooks.

Tomislav currently works as a consultant at Piasevoli Analytics company (www.piasevoli.com) together with his brother Hrvoje. They specialize in Microsoft SQL Server Business Intelligence platform, SSAS primarily, and offer their BI skills worldwide.

In addition to his regular work, Tomislav manages to find the time to present at local conferences or to write an article or two for local magazines. His contribution to the community has been recognized by Microsoft honoring him with the Most Valuable Professional (MVP) award for six consecutive years (2009-2015).

A large portion of this cookbook is present in all editions, therefore I feel obliged to express my gratitude once again to all the people that influenced its contents or helped making it better. They are: Chris Webb, Greg Galloway, Marco Russo, Darren Gosbell, Deepak Puri, Hrvoje Piasevoli, Willfried Färber, Mosha Pasumansky, Teo Lachev, Jeffrey Wang, Jeremy Kashel, Vidas Matelis, Thomas Kejser, Jeff Moden, Michael Coles, Itzik Ben-Gan, Irina Gorbach, Vincent Rainardi, and my ex-colleagues at SoftPro Tetral company. Next, I appreciate Packt Publishing for giving me a chance to write the first edition of this book. In this third edition, I am thankful to Sumeet Sawant and Tushar Gupta for their help and patience. Dave Wentzel deserves a big thank you for making sure the recipes make sense and that they are laid out in an understandable and clear way. A huge thank you goes to Sherry Li, my dear partner in this project. Her friendly attitude and willingness to help meant a lot to me while I was struggling with some recipes. Speaking of recipes, there were few bright people that took significant part in forcing me to rethink the recipes repeatedly and, in that way, either inspired me or helped me make them better. They are: Snježana Škledar, Aleš Plavčák, Hrvoje Gabelica, and Philipp Trannacher. Thank you, guys! Finally, a thank you goes to my family, close friends, business partners, and clients for understanding why I partially neglected you while working on the book. I dedicate this book to my children, Petra, Matko, and Nina.

Sherry Li is an Analytic Consultant who works for a major financial organization with responsibilities in implementing data warehousing, Business Intelligence, and business reporting solutions. She specializes in automation and optimization of data gathering, storing, analyzing and providing data access for business to gain data-driven insights. She especially enjoys sharing her experience and knowledge in data ETL process, database design, dimensional modeling, and reporting in T-SQL and MDX. She has co-authored two books, the MDX with SSAS 2012 Cookbook and MDX with Microsoft SQL Server 2016 Analysis Services Cookbook, which have helped many data professionals advanced their MDX skill in a very short time. Sherry Li maintains her blog at bisherryli.com.

This book is dedicated to readers who are enthusiastic about Multidimensional modeling and MDX (Multi-Dimensional eXpressions). What I love to do the most is share knowledge, so it is wonderful knowing that the MDX Cookbook is a popular book! Readers who want to become proficient in MDX have given tremendous responses to the first two editions of the book. There is nothing that satisfies me more than knowing that this 2016 edition have even more to share with the readers. I owe tremendous thanks to Packt Publishing for giving me another opportunity to write this edition of the MDX Cookbook. Their first-class professionalism in book designing, editing, publishing and collaboration has impressed me during the entire book project. Special thanks to Sumeet Sawant who is a wonderful content editor, and Tushar Gupta who initiated the project.

Three years ago I was daring enough to take the challenge of working on the second edition of the MDX Cookbook. This third edition has brought me once again working side-by-side with Tomislav Piasevoli, who had this bold idea of adding two new chapters with contents that were never fully presented before in previous MDX books. His dedication to the readers and attention to details left me with a great impression. This 2016 edition would not be possible without his leadership. Thank you Tomislav for your commitment to collaboration, encouragement, and deep knowledge of MDX and cube design. I look forward to future collaboration. To Dave Wentzel, for your insight, helpful questioning, ("Can you give an example or screenshot of this? This may be difficult to conceptually follow for the novice.") and encouraging comments ("Good explanation. Seems important enough to call out in a tip box or something else to visually note it is important.").

Thanks to all my friends, especially my ACSE (Association of Chinese-American Scientists and Engineers) friends for sharing my sense of accomplishment. To my co-workers, current and past, for their earnest encouragement, enthusiasm, and feedbacks. Last and foremost, I want to thank my husband Jim and daughter Shasha, for all of the support they have given to me. All of the MDX Cookbook work occurred on weekends, nights, and other times inconvenient to my family. To my daughter, for also being my English grammar teacher.

To my dog Atari, for always sitting by my feet while I write late at night.

About the Reviewer

Dave Wentzel is a Data Solutions Architect for Microsoft. He helps customers with their Azure Digital Transformation, focused on data science, big data, and SQL Server. After working with customers, he provides feedback and learnings to the product groups at Microsoft to make better solutions. Dave has been working with SQL Server for many years, and with MDX and SSAS since they were in their infancy. Dave shares his experiences at <http://davewentzel.com>. He's always looking for new customers. Would you like to engage?

Table of Contents

Chapter 1: Elementary MDX Techniques	12
Introduction	12
Putting data on x and y axes	13
Getting ready	14
How to do it...	15
How it works...	16
There's more...	16
Putting more hierarchies on x and y axes with cross join	16
Skiping axes	18
Getting ready	18
How to do it...	18
How it works...	19
There's more...	19
The idea behind it	20
Possible workarounds – dummy column	21
Using a WHERE clause to filter the data returned	21
Getting ready	21
How to do it...	22
How it works...	23
There's more...	24
Optimizing MDX queries using the NonEmpty() function	25
Getting ready	25
How to do it...	26
How it works...	26
There's more...	27
NonEmpty() versus NON EMPTY	28
Common mistakes and useful tips	28
Using the Properties() function to retrieve data from attribute relationships	29
Getting ready	30
How to do it...	32
How it works...	33
There's more...	34
Basic sorting and ranking	35
Getting ready	36

How to do it...	36
How it works...	40
There's more...	40
Handling division by zero errors	41
Getting ready	41
How to do it...	42
How it works...	43
There's more...	44
Earlier versions of SSAS	44
Setting a default member of a hierarchy in the MDX script	44
Getting ready	45
How to do it...	46
How it works...	46
There's more...	46
Helpful tips	49
Chapter 2: Working with Sets	50
Introduction	50
Implementing the NOT IN set logic	51
Getting ready	51
How to do it...	52
How it works...	53
There's more...	54
See also	54
Implementing the logical OR on members from different hierarchies	55
Getting ready	56
How to do it...	57
How it works...	58
There's more...	59
A special case of a non-aggregatable dimension	59
A very complex scenario	60
See also	60

How to do it...	84
How it works...	86
There's more...	87
Useful string functions	88
See also	88
Implementing the logical AND on members from the same hierarchy	88
Getting ready	89
How to do it...	91
How it works...	93
There's more...	95
Where to put what?	95
A very complex scenario	96
See also	96
Chapter 3: Working with Time	97
Introduction	97
Calculating the year-to-date (YTD) value	98
Getting ready	99
How to do it...	99

How it works...	101
There's more...	101
Inception-To-Date calculation	102
Using the argument in the YTD() function	103
Common problems and how to avoid them	103
YTD() and future dates	105
See also	106
Calculating the year-over-year (YoY) growth (parallel periods)	106
Getting ready	106
How to do it...	107
How it works...	108
There's more...	109
ParallelPeriod is not a time-aware function	111
See also	112
Calculating moving averages	112
Getting ready	113
How to do it...	113
How it works...	114
There's more...	115
Other ways to calculate the moving averages	116
Moving averages and the future dates	116
Finding the last date with data	117
Getting ready	117
How to do it...	118
How it works...	120
There's more...	120
See also	122
Getting values on the last date with data	122
Getting ready	122
How to do it...	123
How it works...	125
There's more...	125
Formatting members on the Date dimension properly	126
Optimizing time-non-sensitive calculations	127
Calculating today's date using the string functions	127
Getting ready	128
How to do it...	128
How it works...	131
There's more...	133
Relative periods	134
Potential problems	134

See also	135
Calculating today's date using the MemberValue function	135

Calculating the difference between two times	145
Getting ready	146
How to do it...	146
How it works...	147
There's more...	147
Formatting the duration	147
Examples of formatting the duration on the Web	148
Counting working days only	148
See also	148
Calculating parallel periods for multiple dates in a set	149
Getting ready	149
How to do it...	151
How it works...	152
There's more...	153
Parameters	154
Reporting covered by design	154
See also	154

Calculating parallel periods for multiple dates in a slicer	154
Getting ready	155
How to do it...	155
How it works...	157
There's more...	158
See also	160
Chapter 4: Concise Reporting	161
Introduction	161
Isolating the best N members in a set	162
Getting ready	163
How to do it...	164
How it works...	165
There's more...	165
The top N members is evaluated in All Periods, not in the context of the opposite query axis	165
The top N members will be evaluated in the context of the slicer	167
Using a tuple in the third argument of the TopCount() function to overwrite the member on the slicer	168
Testing the correctness of the result	169
Multidimensional sets	170
TopPercent() and TopSum() functions	170
See also	170
Isolating the worst N members in a set	170
Getting ready	171
How to do it...	171
How it works...	173
There's more...	174
See also	174
Identifying the best/worst members for each member of another hierarchy	174
Getting ready	174
How to do it...	176
How it works...	177
There's more...	178
Support for the relative context and multidimensional sets in SSAS frontends	180
See also	181
Displaying a few important members, with the others as a single row, and the total at the end	181
Getting ready	182
How to do it...	182

How it works...	184
There's more...	185
Making the query even more generic	185
See also	186
Combining two hierarchies into one	186
Getting ready	187
How to do it...	188
How it works...	189
There's more...	191
Use it, but don't abuse it	191
Limitations	192
Finding the name of a child with the best/worst value	192
Getting ready	192
How to do it...	194
How it works...	195
There's more...	196
Variations on a theme	198
Displaying more than one member's caption	198
See also	198
Highlighting siblings with the best/worst values	198
Getting ready	198
How to do it...	200
How it works...	202
There's more...	202
Troubleshooting	205
See also	205
Implementing bubble-up exceptions	205
Getting ready	206
How to do it...	206
How it works...	208
There's more...	208
Practical value of bubble-up exceptions	210
Potential problems	211
See also	211
Chapter 5: Navigation	212
 Introduction	212
 Detecting a particular member in a hierarchy	213
Getting ready	214
How to do it...	215
How it works...	216

There's more...	216
Important remarks	217
Comparing members versus comparing values	217
Detecting complex combinations of members	218
See also	218
Detecting the root member	219
Getting ready	219
How to do it...	220
How it works...	221

Preface

Microsoft SQL Server Analysis is one of the keystones of Microsoft's Business Intelligence (BI) product strategy. It is the most widely deployed OLAP server around the world. Many organizations, both large and small, have adopted it to provide secure and high-performance access to complex analytics.

MDX (for Multi-Dimensional eXpressions) is the BI industry standard for multidimensional calculations and queries, and is the most widely accepted software language in multidimensional data warehouse. Proficiency with MDX is essential for any professionals who work with multidimensional cubes. MDX is an elegant and powerful language, but also has a steep learning curve.

SQL Server 2012 Analysis Services has introduced a new BISM tabular model and a new formula language, Data Analysis Expressions (DAX). However, for the multi-dimensional model, MDX is still the only query and expression language. For many product developers and report developers, MDX still is and will be the preferred language for both the tabular model and the multi-dimensional model.

SQL Server 2016 is the biggest leap forward in Microsoft's data platform history. SQL Server 2016 Analysis Services has also come with some great improvements and features for Multidimensional model. The DirectQuery mode can now be used to connect directly to SQL Server, SQL Server Parallel Data Warehouse (Microsoft Analytics Platform System), Oracle and Teradata. The DirectQuery mode has also significantly improved performance compared to the previous version. The SQL Server 2012 Management Studio (SSMS) came with a graphical user interface to configure and manage Extended Events within SQL Server Database Engine. Now this is also available for SQL Server 2016 Analysis Services. The Extended Events support through SSMS GUI allows a simplified way of monitoring your Analysis Services 2016 instances, both Tabular and Multidimensional.

Despite its popularity, very few books are dedicated to MDX. MDX-related books often limit their content to explaining the concepts of multidimensional cubes, the MDX language concept and its functions, and other specifics related to working with Analysis Services.

This book presents MDX solutions for business requirements that can be found in the real business world. You will find best practices, explanations of advanced subjects in full detail, and deep knowledge in every topic. Organized around practical MDX solutions, this book provides full, in-depth treatment of each topic, sequenced in a logical progression from elementary to advanced techniques.

This book is written in a cookbook format. You can browse through the contents and look for solutions to a particular problem. Each recipe is relatively short and grouped by relevancy, so you can find solutions to related issues in one place. Related recipes are sequenced in a logical progression; you will be able to build up your understanding of the topic incrementally.

This book is designed for both beginners and experts in MDX. If you are a beginner, this book is a good place to start. Each recipe provides you with best practices and their underlying rationale, detailed sample scripts, and options you need to know to make good choices. If you are an expert, you will be able to use this book as a reference. Whenever you face a particular challenge, you will be able to find a chapter that is dedicated to the topic.

We hope that you will become confident not only in using the sample MDX queries, but also in creating your own solutions. The moment you start creating your own solutions by combining techniques presented in this book, our goal of teaching through examples is accomplished. We want to hear from you about your journey to MDX proficiency. Feel free to contact us.

What this book covers

We added two new chapters to this edition of MDX cookbook: *Chapter 6, MDX for Reporting*, and *Chapter 9, Metadata - Driven Calculations*. We also decided to remove *Chapter 8, Advanced MDX Topics* due to many overlapping and redundant recipes.

To turn ad-hoc reports into parameterized reports is a challenging task. There are many special considerations associated with the dynamic nature of the reports with dynamic parameters. Through carefully thought-out examples, *Chapter 6, MDX for Reporting*, introduces new concepts in dynamic reporting, the challenges and the techniques for efficient report writing.

Once a cube is designed and implemented, adding more calculations is a common requirement. These calculations are defined not by the data of the cube, but by expressions that can reference other parts of the cube. MDX calculations that are metadata-driven let us extend the capabilities of a cube, adding flexibility and power to business intelligence solutions. It also comes with challenges, of having instead complex calculations. *Chapter 9, Metadata-driven Calculations* will cover techniques and best practices that have never been fully documented in any MDX books before.

Here's an overview of chapters and their contents.

Chapter 1, *Elementary MDX Techniques*, uses simple examples to demonstrate the fundamental MDX concepts, features, and techniques that are the foundations for our further explorations of the MDX language.

Chapter 2, *Working with Sets*, focuses on the challenges of performing logic operations, NOT, OR and AND, on manipulating sets in general.

Chapter 3, *Working with Time*, presents various time-related functions in MDX that are designed to work with a special type of dimension called Time and its typed attributes.

Chapter 4, *Concise Reporting*, focuses on techniques that you can employ in your project to make analytical reports more compact and more concise, and therefore, more efficient.

Chapter 5, *Navigation*, shows common tasks and techniques related to navigation and data retrieval relative to the current context.

Chapter 6, *MDX for Reporting*, covers common MDX reporting requirements and techniques using two approaches: parameterized MDX queries and dynamic MDX queries.

Chapter 7, *Business Analytics*, focuses on performing typical business analyses, such as forecasting, allocating values, and calculating the number of days from the last sales date.

Chapter 8, *When MDX is Not Enough*, teaches you that MDX calculations are not always the place to look for solutions. It illustrates several techniques to optimize the query response times with a relatively simple change in cube structure.

Chapter 9, *Metadata-driven Calculations*, explores the concept of storing and maintaining MDX calculations outside the cube by utilizing reporting dimension, custom aggregations, scopes and assignments.

Chapter 10, *On the Edge*, presents topics that will expand your horizons, such as clearing cache for performance tuning, executing MDX queries in T-SQL environment, using SSAS Dynamic Management Views (DMVs), drill-through, and capturing MDX queries using SQL Server Profiler.

What you need for this book

A Microsoft SQL Server 2016 full installation or at least the following components are required:

- SQL Server 2016 Engine
- Analysis Services 2016
- Microsoft SQL Server Management Studio
- Microsoft SQL Server Data Tools

We recommend the Developer, Enterprise, or the Trial Edition of Microsoft SQL Server 2016. Standard Edition is not recommended because it does not support all the features and a few examples might not work using the Standard Edition.

The Developer Edition has the full capabilities of the Enterprise Edition and is for development and testing only. The Developer Edition is free if you sign up for the free Visual Studio Dev Essentials program. To download the SQL Server 2016 Developer Edition free, you can start from joining or accessing the Visual Studio Dev Essentials site:

<https://www.visualstudio.com/dev-essentials/>

You can also access it from this tiny url:

<http://tinyurl.com/zzpzdwv>

Microsoft SQL Server 2016 Trial Edition is for evaluation only and is valid for 180 days. Use this link to go to Microsoft Evaluation Center:

<http://tinyurl.com/joap9rh>

Both the relational database file and the multidimensional Adventure Works project files are required:

- AdventureWorks Sample Databases and Scripts for SQL Server 2016: this is the relational database; use this link to download the AdventureWorks databases and scripts: <http://tinyurl.com/z8k479p>
- AdventureWorks Multidimensional Model SQL Server 2012 or 2014 - Enterprise Edition: SSAS project files. The 2012 or 2014 tutorials are valid for SQL Server 2016.

We recommend the Enterprise Edition of the Multidimensional Model Adventure Works cube project. To download the installation files, use the following link to go to CodePlex:

<http://tinyurl.com/AdventureWorks2012>

For the 2014 Multidimensional Model Adventure Works cube project, go to Adventure Works 2014 Sample Databases on CodePlex:

<http://tinyurl.com/otj8bxr>

For instructions on how to install the sample Adventure Works, see Install Sample Data and Projects for the Analysis Services Multidimensional Modeling Tutorial at this link:

<http://tinyurl.com/jx6ghbm>

Wide World Importers: The new SQL Server sample database

For the magnitude of SQL Server 2016 Microsoft has released a new sample database, the Wide World Importers database.

Both the 2008 and 2012 edition of the MDX Cookbook has been based off Adventure Works, which has been around since the SQL Server 2005 days. For the purpose of demonstrating MDX techniques and Analysis Services features, the Adventure Works sample database has continued to be a good choice for this 2016 edition.

For Creating PivotTable, see this section:

Microsoft Excel 2007 (or newer) with PivotTable is required.

Most of the examples will work with older versions of Microsoft SQL Server (2005 or 2008 or 2008 R2 or 2012). However, some of them will need adjustments because the Date dimension in the older versions of the Adventure Works database has a different set of years. To solve that problem, simply shift the date-specific parts of the queries few years back in time, for example, turn the year 2013 into the year 2002 and Q3 of the year 2013 to Q3 of 2003.

Who this book is for

This is a book for multidimensional cube developers and multidimensional database administrators, for report developers who write MDX queries to access multidimensional cubes, for power users and experienced business analysts. All of the will find this book invaluable.

In other words, this book is for anyone who works with multidimensional cubes, who finds himself or herself in situations feeling difficult to deliver what end users ask for or who are interested in getting more out of their multidimensional cubes. This book is for you if you have found yourself in situations where it is difficult to deliver what your users want and you are interested in getting more information out of your multidimensional cubes.

Sections

In this book, you will find several headings that appear frequently (Getting ready, How to do it, How it works, There's more, and See also).

To give clear instructions on how to complete a recipe, we use these sections as follows:

Getting ready

This section tells you what to expect in the recipe, and describes how to set up any software or any preliminary settings required for the recipe.

How to do it...

This section contains the steps required to follow the recipe.

How it works...

This section usually consists of a detailed explanation of what happened in the previous section.

There's more...

This section consists of additional information about the recipe in order to make the reader more knowledgeable about the recipe.

See also

This section provides helpful links to other useful information for the recipe.

Conventions

In this book, you will find a number of styles of text that distinguish between different kinds of information. Here are some examples of these styles, and an explanation of their meaning.

When shown in text, code words `NONEMPTY()` will be shown as follows: "Optimizing MDX queries using the `NONEMPTY()` function."

A block of code is set as follows:

```
SELECT
{ [Measures].[Reseller Order Quantity],
  [Measures].[Reseller Order Count] } ON 0,
NON EMPTY
{ [Date].[Month of Year].MEMBERS } ON 1
FROM
[Adventure Works]
WHERE
( [Promotion].[Promotion Type].&[New Product] )
```

When we wish to draw your attention to a particular part of a code block, the relevant lines or items are set in bold:

```
SELECT
{ [Measures].[Reseller Sales Amount] } ON 0,
{ ParallelPeriod(
  [Geography].[Geography].[Country],
  2,
  [Geography].[Geography].[State-Province].&[CA]&[US]
)
} ON 1
FROM
[Adventure Works]
```

New terms and **important words** are shown in bold. Words that you see on the screen, in menus or dialog boxes for example, appear in the text like this: "We can verify this by browsing the **Geography** user hierarchy in the **Geography** dimension in SQL Server Management Studio".

Warnings or important notes appear in an information box like this.

Tips and tricks appear in a tip box like this.

Reader feedback

Feedback from our readers is always welcome. Let us know what you think about this book—what you liked or disliked. Reader feedback is important for us as it helps us develop titles that you will really get the most out of.

To send us general feedback, simply e-mail feedback@packtpub.com, and mention the book's title in the subject of your message.

If there is a topic that you have expertise in and you are interested in either writing or contributing to a book, see our author guide at www.packtpub.com/authors.

Customer support

Now that you are the proud owner of a Packt book, we have a number of things to help you to get the most from your purchase.

Downloading the example code

You can download the example code files for this book from your account at <http://www.packtpub.com>. If you purchased this book elsewhere, you can visit <http://www.packtpub.com/support> and register to have the files e-mailed directly to you.

You can download the code files by following these steps:

1. Log in or register to our website using your e-mail address and password.
2. Hover the mouse pointer on the **SUPPORT** tab at the top.
3. Click on **Code Downloads & Errata**.
4. Enter the name of the book in the **Search** box.
5. Select the book for which you're looking to download the code files.
6. Choose from the drop-down menu where you purchased this book from.
7. Click on **Code Download**.

You can also download the code files by clicking on the **Code Files** button on the book's webpage at the Packt Publishing website. This page can be accessed by entering the book's name in the **Search** box. Please note that you need to be logged in to your Packt account.

Once the file is downloaded, please make sure that you unzip or extract the folder using the latest version of:

- WinRAR / 7-Zip for Windows
- Zipeg / iZip / UnRarX for Mac
- 7-Zip / PeaZip for Linux

The code bundle for the book is also hosted on GitHub at <https://github.com/PacktPublishing/MDX-with-Microsoft-SQL-Server-2016-Analysis-Services-Cookbook>. We also have other code bundles from our rich catalog of books and videos available at <https://github.com/PacktPublishing/>. Check them out!

Downloading the color images of this book

We also provide you with a PDF file that has color images of the screenshots/diagrams used in this book. The color images will help you better understand the changes in the output.

You can download this file from

https://www.packtpub.com/sites/default/files/downloads/MDXwithMicrosoftSQLServer2016AnalysisServicesCookbook_ColorImages.pdf.

Errata

Although we have taken every care to ensure the accuracy of our content, mistakes do happen. If you find a mistake in one of our books-maybe a mistake in the text or the code-we would be grateful if you could report this to us. By doing so, you can save other readers from frustration and help us improve subsequent versions of this book. If you find any errata, please report them by visiting <http://www.packtpub.com/submit-errata>, selecting your book, clicking on the **Errata Submission Form** link, and entering the details of your errata. Once your errata are verified, your submission will be accepted and the errata will be uploaded to our website or added to any list of existing errata under the Errata section of that title.

To view the previously submitted errata, go to <https://www.packtpub.com/books/content/support> and enter the name of the book in the search field. The required information will appear under the **Errata** section.

Piracy

Piracy of copyrighted material on the Internet is an ongoing problem across all media. At Packt, we take the protection of our copyright and licenses very seriously. If you come across any illegal copies of our works in any form on the Internet, please provide us with the location address or website name immediately so that we can pursue a remedy.

Please contact us at copyright@packtpub.com with a link to the suspected pirated material.

We appreciate your help in protecting our authors and our ability to bring you valuable content.

Questions

If you have a problem with any aspect of this book, you can contact us at questions@packtpub.com, and we will do our best to address the problem.

1

Elementary MDX Techniques

In this chapter, we will cover the following recipes:

- Putting data on *x* and *y* axes
- Skipping axes
- Using a WHERE clause to filter the data returned
- Optimizing MDX queries using the NonEmpty() function
- Using the Properties() function to retrieve data from attribute relationships
- Basic sorting and ranking
- Handling division by zero errors
- Setting a default member of a hierarchy in the MDX script

Introduction

MDX is an elegant and powerful language, but also has a steep learning curve.

The goal of this chapter is to use some simple examples to demonstrate the fundamental MDX concepts, features, and techniques that are the foundations for further exploration of the MDX language.

The chapter begins with several basic techniques: putting multi-dimensional data onto query axes, cube space restriction, empty cell removal, and the important concept of unique names for members, tuples, and sets. From there, we shall turn our attention to a few more advanced features, such as using the MDX functions, creating calculations in the cube space, manipulating strings, writing parameterized queries, and conditionally formatting cell properties. This will form the basis for the rest of the chapters in this book.

SSAS 2016 provides a sample **Analysis Services database**, the **Multidimensional Adventure Works DW**. All the MDX queries and scripts in this book have been updated for Analysis Services 2016, and verified against the 2016 Enterprise Edition of the Adventure Works DW Analysis Services database. The majority of the MDX queries and scripts should also run and have been tested in SSAS 2008 R2 and also SSAS2012.

The **Query Editor** in **SQL Server Management Studio (SSMS)** is our choice for writing and testing MDX queries. SQL Server 2012 and 2016 come with a free tool: **SQL Server Data Tools (SSDT)** for cube developers. Just as the **Business Intelligence Development Studio (BIDS)** was the tool that we used for cube design and MDX scripting in SSAS 2008, SSDT is the tool we will use in this cookbook for cube design and MDX scripting for SSAS 2016.

Putting data on x and y axes

Cube space in SSAS is multi-dimensional. MDX allows you to display results on axes from 0, 1, and 2, up to 128. The first five axes have aliases: COLUMNS, ROWS, PAGES, SECTIONS, and CHAPTERS. However, the frontend tools such as SQL Server Management Studio (SSMS) or other applications that you can use for writing and executing MDX queries only have two axes, the *x* and *y* axes, or COLUMNS and ROWS.

As a result, we have two tasks to do when trying to fit the multi-dimensional data onto the limited axes in our frontend tool:

- We must always explicitly specify a display axis for all elements in the SELECT list. We can use aliases for the first five axes: COLUMNS, ROWS, PAGES, SECTIONS, and CHAPTERS. We are also allowed to use integers, 0, 1, 2, 3, and so on but we are not allowed to skip axes. For example, the first axis must be COLUMNS (or 0). ROWS (or 1) cannot be specified unless COLUMNS (or 0) has been specified first.
- Since we only have two display axes to show our data, we must be able to *combine* multiple hierarchies into one query axis. In MDX and other query language terms, we call it *crossjoin*.

It is fair to say that your job of writing MDX queries is mostly trying to figure out how to project multi-dimensional data onto only two axes, namely, *x* and *y*. We will start by putting only one hierarchy on COLUMNS, and one on ROWS. Then we will use the `Crossjoin()` function to combine more than one hierarchy into COLUMNS and ROWS.

Getting ready

Making a two-by-eight table (that is shown following) in a spreadsheet is quite simple. Writing an MDX query to do that can also be very simple. Putting data on the *x* and *y* axes is a matter of finding the right expressions for each axis:

	Internet Sales Amount
Australia	\$9,061,000.58
Canada	\$1,977,844.86
France	\$2,644,017.71
Germany	\$2,894,312.34
NA	(null)
United Kingdom	\$3,391,712.21
United States	\$9,389,789.51

All we need are three things from our cube:

- The name of the cube
- The correct expression for the Internet Sales Amount so we can put it on the columns
- The correct expression of the sales territory so we can put it on the rows

Once we have the preceding three things, we are ready to plug them into the following MDX query, and the cube will give us back the two-by-eight table:

```
SELECT  
    [The Sales Expression] ON COLUMNS,  
    [The Territory Expression] ON ROWS  
FROM  
    [The Cube Name]
```

The MDX engine will understand it perfectly, if we replace columns with 0 and rows with 1. Throughout this book, we will use the number 0 for columns, which is the *x* axis, and 1 for rows, which is the *y* axis.

How to do it...

We are going to use the Adventure Works 2016 Multidimensional Analysis Service database enterprise edition in our cookbook. If you open the Adventure Works cube, and hover your cursor over the Internet Sales Amount measure, you will see the fully qualified expression, [Measures].[Internet Sales Amount]. This is a long expression. Drag and drop in SQL Server Management Studio works perfectly for us in this situation.

Long expressions are a fact of life in MDX. Although the case does not matter, correct spelling is required, and fully qualified and unique expressions are recommended for MDX queries to work properly.

Follow these two steps to open the Query Editor in SSMS:

1. Start SQL Server Management Studio (SSMS) and connect to your SQL Server Analysis Services (SSAS) 2016 instance (localhost or servername\instancename).
2. Click on the target database Adventure Works DW 2016, and then right-click on the **New Query** button.

Follow these steps to save the time spent for typing the long expressions:

1. Put your cursor on [Measures].[Internet Sales Amount], and drag and drop it onto AXIS(0).
2. To get the proper expression for the sales territory, put your cursor over the [Sales Territory Country] under the **Sales Territory | Sales Territory Country**. Again, this is a long expression. Drag-and-drop it onto AXIS(1).
3. For the name of the cube, the drag-and-drop should work too. Just point your cursor to the cube name, and drag-and-drop it in your FROM clause.

This should be your final query:

```
SELECT  
    [Measures].[Internet Sales Amount] ON 0,  
    [Sales Territory].[Sales Territory Country].[Sales Territory  
        Country] ON 1  
FROM  
    [Adventure Works]
```

Downloading the example code:

You can download the example code files for all Packt books you have purchased from your account at <http://www.packtpub.com>. If you purchased this book elsewhere, you can visit <http://www.packtpub.com/support> and register to have the files e-mailed directly to you.

When you execute the query, you should get a two-by-eight table, the same as in the following screenshot:

	Internet Sales Amount
Australia	\$9,061,000.58
Canada	\$1,977,844.86
France	\$2,644,017.71
Germany	\$2,894,312.34
NA	(null)
United Kingdom	\$3,391,712.21
United States	\$9,389,789.51

How it works...

We have chosen to put Internet Sales Amount on the AXIS(0), and all members of Sales Territory Country on the AXIS(1). We have fully qualified the measure with the special dimension [Measures], and the sales territory members with dimension [Sales Territory] and hierarchy [Sales Territory Country].

You might have expected an aggregate function such as SUM somewhere in the query. We do not need to have any aggregate function here because the cube understands that when we ask for the sales amount for Canada, we would expect the sales amount to come from all the provinces and territories in Canada.

There's more...

SSAS cubes are perfectly capable of storing data in more than two dimensions. In MDX, we can use the technique called *crossjoin* to combine multiple hierarchies into one query axis.

Putting more hierarchies on x and y axes with cross join

In an MDX query, we can specify how multi-dimensions from our SSAS cube lay out onto only two *x* and *y* axes. Cross-joining allows us to get every possible combination of two lists in both SQL and MDX.

We wish to write an MDX query to produce the following table. On the columns axis, we want to see both **Internet Sales Amount** and **Internet Gross Profit**. On the rows axis, we want to see all the sales territory countries, and all the products sold in each country:

		Internet Sales Amount	Internet Gross Profit
Australia	Accessories	\$138,690.63	\$86,820.10
Australia	Bikes	\$8,852,050.00	\$3,572,267.29
Australia	Clothing	\$70,259.95	\$26,767.68
Australia	Components	(null)	(null)
Canada	Accessories	\$103,377.85	\$64,714.37
Canada	Bikes	\$1,821,302.39	\$741,451.22
Canada	Clothing	\$53,164.62	\$23,755.91
Canada	Components	(null)	(null)

This query lays two measures on columns from the same dimension [**Measures**], and two different hierarchies; [**Sales Territory Country**] and [**Product Categories**] on rows:

```
SELECT
    { [Measures].[Internet Sales Amount],
      [Measures].[Internet Gross Profit]
    } ON 0,
    { [Sales Territory].[Sales Territory Country].[Sales Territory
      Country] *
      [Product].[Product Categories].[Category]
    } ON 1
FROM
    [Adventure Works]
```

To return the cross-product of two sets, we can use either of the following two syntaxes:

Standard syntax: Crossjoin(Set_Expression1, Set_Expression2)

Alternate syntax: Set_Expression1 * Set_Expression2

We have chosen to use the alternate syntax for its convenience. The result from the previous query is shown as follows:

		Internet Sales Amount	Internet Gross Profit
Australia	Accessories	\$138,690.63	\$86,820.10
Australia	Bikes	\$8,852,050.00	\$3,572,267.29
Australia	Clothing	\$70,259.95	\$26,767.68
Australia	Components	(null)	(null)
Canada	Accessories	\$103,377.85	\$64,714.37
Canada	Bikes	\$1,821,302.39	\$741,451.22
Canada	Clothing	\$53,164.62	\$23,755.91

Skipping axes

There are situations where we want to display just a list of members with no data associated with them. Naturally, we expect to get that list in rows, so that we can scroll through them vertically instead of horizontally. However, the rules of MDX say that we can't skip the axes. If we want something on rows (which is `AXIS(1)` by the way), we must use all previous axes as well (columns in this case, which is also known as `AXIS(0)`).

The reason why we want the list to appear on axis 1 and not axis 0 is because a horizontal list is not as easy to read as a vertical one.

Is there a way to display those members on rows and have nothing on columns? Sure! This recipe shows how.

Getting ready

The notation for an empty set is this: `{ }`. So for the axis 0, we would simply do this:

```
{ } ON 0
```

How to do it...

Follow these steps to open the Query Editor in SQL Server Management Studio (SSMS):

1. Start SQL Server Management Studio (SSMS) and connect to your SQL Server Analysis Services (SSAS) 2012 instance.
2. Click on the target database, Adventure Works DW 2016, and then right-click on the **New Query** button.

Follow these steps to get a one-dimensional query result with members on rows:

1. Put an empty set on columns (`AXIS(0)`). The notation for the empty set is this:
`{ }.`
2. Put some hierarchy on rows (`AXIS(1)`). In this case, we used the largest hierarchy available in this cube—customer hierarchy of the same dimension.
3. Run the following query:

```
SELECT
    { } ON 0,
    { [Customer].[Customer].[Customer].MEMBERS } ON 1
FROM
    [Adventure Works]
```

How it works...

Although we can't skip axes, we are allowed to provide an empty set on them. This trick allows us to get what we need—nothing on columns and a set of members on rows.

There's more...

Skipping the `AXIS(0)` is a common technique to create a list for report parameters. If we want to create a list of customers whose name contains `John`, we can modify the preceding base query to use two functions to get only those customers whose name contains the phrase `John`. These two functions are `Filter()` and `InStr()`:

```
SELECT
    { } ON 0,
    { Filter(
        [Customer].[Customer].[Customer].MEMBERS,
        InStr(
            [Customer].[Customer].CurrentMember.Name,
```

```
'John'  
    ) > 0  
)  
} ON 1  
FROM  
[Adventure Works]
```

In the final result, you will notice the John phrase in various positions in member names:

Abigail Johnson
Alexander M. Johnson
Alexandra J. Johnson
Alexis J. Johnson
Alyssa K. Johnson
Andrew F. Johnson
Anna Johnson
Anthony D. Johnson

The idea behind it

Instead of skipping the `AXIS(0)`, if you put a cube measure or a calculated measure with a non-constant expression on axis 0, you will slow down the query. The slower query time can be noticeable if there are a large number of members from the specified hierarchy. For example, if you put the Sales Amount measure on axis 0, the Sales Amount will have to be evaluated for each member in the rows. Do we need the Sales Amount? No, we don't. The only thing we need is a list of members; hence we have used an empty set {} on `AXIS(0)`. That way, the SSAS engine does not have to go into cube space to evaluate the sales amount for every customer. The SSAS engine will only reside in dimension space, which is much smaller, and the query is therefore more efficient.

Possible workarounds – dummy column

Some client applications might have issues with the MDX statement skipping axes because they expect something on columns, and will not work with an empty set on axis 0. In this case, we can define a constant measure (a measure returning null, 0, 1, or any other constant) and place it on columns. In MDX's terms, this constant measure is a calculated measure. It will act as a dummy column. It might not be as efficient as an empty set, but it is a much better solution than the one with a regular (non-constant) cube measure like the Sales Amount measure.

This query creates a dummy value on columns:

```
WITH
MEMBER [Measures].[Dummy] AS NULL

SELECT
{ [Measures].[Dummy] } ON 0,
{ [Customer].[Customer].[Customer].MEMBERS } ON 1
FROM
[Adventure Works]
```

Using a WHERE clause to filter the data returned

A WHERE clause in MDX works in a similar way as the other query languages. It acts as a filter and restricts the data returned in the result set.

Not surprisingly, however, the WHERE clause in MDX does more than just restricting the result set. It also establishes the *query context*.

Getting ready

The MDX WHERE clause points to a specific intersection of cube space. We use tuple expressions to represent cells in cube space. Each tuple is made up of one member, and only one member, from each hierarchy.

The following tuple points to one year, 2013 and one measure, the [Internet Sales Amount]:

```
( [Measures].[Internet Sales Amount],  
  [Date].[Calendar Year].&[2013]  
)
```

Using a tuple in an MDX WHERE clause is called *slicing* the cube. This feature gives the WHERE clause another name, slicer. If we put the previous tuple in the WHERE clause, in MDX terms, we are saying, *show me some data from the cube sliced by sales and the year 2013.*

That is what we are going to do next.

How to do it...

Open the Query Editor in SSMS, and then follow these steps to write a query with a slicer and test it:

1. Copy this initial query into the Query Editor and run the query.

```
SELECT  
{ [Customer].[Customer Geography].[Country]  
} ON 0,  
{ [Product].[Product Categories].[Category] } ON 1  
FROM  
[Adventure Works]
```

You will see the following result:

	Australia	Canada	France	Germany	
Accessories	\$571,297.93	\$571,297.93	\$571,297.93	\$571,297.93	
Bikes	\$66,302,381.56	\$66,302,381.56	\$66,302,381.56	\$66,302,381.56	
Clothing	\$1,777,840.84	\$1,777,840.84	\$1,777,840.84	\$1,777,840.84	
Components	\$11,799,076.66	\$11,799,076.66	\$11,799,076.66	\$11,799,076.66	

2. At this point, we should ask the question, *What are the cell values?* The cell values are actually the [Measures].[Reseller Sales Amount], which is the default member on the Measures dimension.

3. Add the previous tuple to the query as a slicer. Here is the final query:

```
SELECT
    { [Customer].[Customer Geography].[Country]
    } ON 0,
    { [Product].[Product Categories].[Category] } ON 1
FROM
    [Adventure Works]
WHERE
    ( [Measures].[Internet Sales Amount],
    [Date].[Calendar Year].&[2013]
)
```

4. The result should be as shown in the following screenshot:

	Australia	Canada	France	Germany	Unit
Accessories	\$132,763.21	\$96,922.04	\$60,599.81	\$59,388.39	\$
Bikes	\$4,139,720.96	\$938,654.76	\$1,491,724.96	\$1,679,892.32	\$2,
Clothing	\$66,959.21	\$50,055.85	\$26,187.03	\$22,595.65	\$1,
Components	(null)	(null)	(null)	(null)	

5. Ask the question again; *What are the cell values?* The cell values are now the [Measures].[Internet Sales Amount], and no longer the default measure.

How it works...

We can slice the data by pointing to a specific intersection of cube space. We can achieve this by putting a tuple in the WHERE clause.

In the preceding example, the cube space is sliced by sales and the year 2008. The cell values are the Internet Sales Amount for each country and each product category, sliced by the year 2008.

There's more...

Notice that the data returned on the query axes can be completely different from the tuple in the WHERE clause. The tuples in the slicer will only affect the cell values in the intersection of rows and columns, not what are on the column or row axes.

If you need to display sales and year 2008 on the query axes, you would need to move them to the query axes, and not in the WHERE clause.

This query has moved the sales to the columns axis, and the year 2008 to the rows axis. They are both *cross joined* to the original hierarchies on the two query axes:

```
SELECT
    { [Measures].[Internet Sales Amount] *
      [Customer].[Customer Geography].[Country]
    } ON 0,
    { [Date].[Calendar Year].&[2013] *
      [Product].[Product Categories].[Category]
    } ON 1
FROM
    [Adventure Works]
```

Run the query and you will get the following result. The cell values are the same as before, but now we have the year 2013 on the rows axis, and the Internet Sales Amount on the columns axis:

		Internet Sales Amount	Internet Sales Amount	Internet Sales Amount	
		Australia	Canada	France	
CY 2013	Accessories	\$132,763.21	\$96,922.04	\$60,599.81	
CY 2013	Bikes	\$4,139,720.96	\$938,654.76	\$1,491,724.96	
CY 2013	Clothing	\$66,959.21	\$50,055.85	\$26,187.03	
CY 2013	Components	(null)	(null)	(null)	

Optimizing MDX queries using the NonEmpty() function

The `NonEmpty()` function is a very powerful MDX function. It is primarily used to improve query performance by reducing sets before the result is returned.

Both `Customer` and `Date` dimensions are relatively large in the Adventure Works DW 2016 database. Putting the cross product of these two dimensions on the query axis can take a long time. In this recipe, we will show how the `NonEmpty()` function can be used on the `Customer` and `Date` dimensions to improve the query performance.

Getting ready

Start a new query in SSMS and make sure that you are working on the Adventure Works DW 2016 database. Then write the following query and execute it:

```
SELECT
    { [Measures].[Internet Sales Amount] } ON 0,
    NON EMPTY
    Filter(
        { [Customer].[Customer].[Customer].MEMBERS } *
        { [Date].[Date].[Date].MEMBERS },
        [Measures].[Internet Sales Amount] > 1000
    ) ON 1
FROM
    [Adventure Works]
```

The query shows the sales per customer and dates of their purchases, and isolates only those combinations where the purchase was over 1,000 USD.

On a typical server, it will take more than a minute before the query will return the results.

Now let us see how to improve the execution time by using the `NonEmpty()` function.

How to do it...

Follow these steps to improve the query performance by adding the NonEmpty() function:

1. Wrap NonEmpty() function around the cross join of customers and dates so that it becomes the first argument of that function.
2. Use the measure on columns as the second argument of that function.
3. This is what the MDX query should look like:

```
SELECT
    { [Measures].[Internet Sales Amount] } ON 0,
NON EMPTY
    Filter(
        NonEmpty(
            { [Customer].[Customer].[Customer].MEMBERS } *
            { [Date].[Date].[Date].MEMBERS },
            { [Measures].[Internet Sales Amount] }
        ),
        [Measures].[Internet Sales Amount] > 1000
    ) ON 1
FROM
    [Adventure Works]
```

4. Execute that query and observe the results as well as the time required for execution. The query returned the same results, only much faster, right?

How it works...

Both the Customer and Date dimensions are medium-sized dimensions. The cross product of these two dimensions contains several million combinations. We know that, typically, the cube space is sparse; therefore, many of these combinations are indeed empty. The Filter() operation is not optimized to work in block mode, which means a lot of calculations will have to be performed by the engine to evaluate the set on rows, whether the combinations are empty or not.

This is because the Filter() function needs to iterate over the complete set of data in every cell in order to isolate a single cell. For this reason, the Filter() function can be slow when operating on large dimensions or cross-join result of even medium-sized dimensions.

The `Filter()` operation is not optimized to work in block mode. It filters a specified set based on a search condition by iterating through each tuple in the specified set. It's a cell-by-cell operation and can be very slow when operating on large dimensions. For a good explanation of the block mode versus cell-by-cell mode, please see *The pluses and minuses of named sets* section of Chapter 5, *Navigation*.

Fortunately, the `NonEmpty()` function exists. This function can be used to reduce any set, especially multidimensional sets that are the result of a *crossjoin* operation.

The `NonEmpty()` function removes the empty combinations of the two sets before the engine starts to evaluate the sets on rows. A reduced set has fewer cells to be calculated, and therefore the query runs much faster.

There's more...

Regardless of the benefits that were shown in this recipe, the `NonEmpty()` function should be used with caution. Here are some good practices regarding the `NonEmpty()` function:

- Use it with sets, such as named sets and axes.
- Use it in the functions which are not optimized to work in block mode, such as with the `Filter()` function.
- Avoid using it in aggregate functions such as `Sum()`. The `Sum()` function and other aggregate functions are optimized to run in block mode. If you pass the data through the `NonEmpty()` the `Sum()` function, which break it into many small non-empty chunks, you will turn this optimization off and those functions will run in a much slower cell-by-cell mode.
- Avoid using it in other MDX set functions that are optimized to work in block mode. The use of the `NonEmpty()` function inside optimized functions will prevent them from evaluating the set in block mode. This is because the set will not be compact once it passes the `NonEmpty()` function. The function will break it into many small non-empty chunks, and each of these chunks will have to be evaluated separately. This will inevitably increase the duration of the query. In such cases, it is better to leave the original set intact, no matter its size. The engine will know how to run over it in optimized mode.

NonEmpty() versus NON EMPTY

Both the `NonEmpty()` function and the `NON EMPTY` keyword can reduce sets, but they do it in a different way.

The `NON EMPTY` keyword removes empty rows, columns, or both, depending on the axis on which that keyword is used in the query. Therefore, the `NON EMPTY` operator tries to push the evaluation of cells to an early stage whenever possible. This way, the set on axis is already reduced and the final result is faster.

Take a look at the initial query in this recipe, remove the `Filter()` function, run the query, and notice how quickly the results come, although the multi-dimensional set again counts millions of tuples. The trick is that the `NON EMPTY` operator uses the set on the opposite axis, the columns, to reduce the set on rows. Therefore, it can be said that `NON EMPTY` is highly dependent on members on axes and their values in columns and rows.

Contrary to the `NON EMPTY` operator found only on axes, the `NonEmpty()` function can be used anywhere in the query.

The `NonEmpty()` function removes all the members from its first set, where the value of one or more measures in the second set is empty. If no measure is specified, the function is evaluated in the context of the current member.

In other words, the `NonEmpty()` function is highly dependent on members in the second set, the slicer, or the current coordinate, in general.

Common mistakes and useful tips

If a second set in the `NonEmpty()` function is not provided, the expression is evaluated in the context of the current measure at the moment of evaluation, and current members of attribute hierarchies, also at the time of evaluation. In other words, if you are defining a calculated measure and you forget to include a measure in the second set, the expression is evaluated for that same measure which leads to null, a default initial value of every measure. If you are simply evaluating the set on the axis, it will be evaluated in the context of the current measure, the default measure in the cube, or the one provided in the slicer. Again, this is perhaps not something you expected. In order to prevent these problems, always include a measure in the second set.

The `NonEmpty()` function reduces sets, just like a few other functions, namely `Filter()` and `Existing()`. But what's special about `NonEmpty()` function is that it reduces sets extremely efficiently and quickly. Because of that, there are some rules about where to position `NonEmpty()` function in calculations made by the composition of MDX functions (one function wrapping the other). If we are trying to detect multi-select, that is, multiple members in the slicer, `NonEmpty()` function should go inside, with the `EXISTING` function/keyword outside. The reason is that although they both shrink sets efficiently, the `NonEmpty()` function works great if the set is intact. The `EXISTING` keyword is not affected by the order of members or compactness of the set. Therefore, the `NonEmpty()` function should be applied earlier.

You may get `System.OutOfMemory` errors if you use the `CrossJoin()` operation on many large hierarchies because the cross join generates a Cartesian product of those hierarchies. In that case, consider using the `NonEmpty()` function to reduce the space to a smaller subcube. Also, don't forget to group the hierarchies by their dimension inside the *cross join*.

Using the `Properties()` function to retrieve data from attribute relationships

Attribute relationships define hierarchical dependencies between attributes. A good example is the relationship between the `City` attribute and the `State` attribute. If we know the current city is Phoenix, we know the state must be Arizona. This knowledge of the relationship, `City/State`, can be used by the Analysis Services engine to optimize performance.

Analysis Services provides the `Properties()` function to allow us to retrieve data based on attribute relationships.

Getting ready

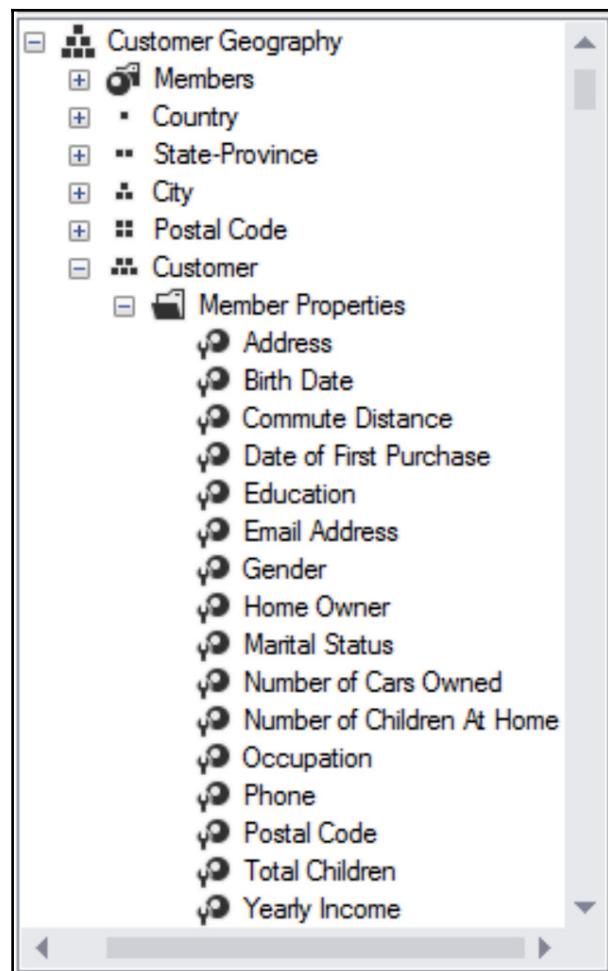

We will start with a classic top 10 query that shows the top 10 customers. Then we will use the `Properties()` function to retrieve each top 10 customer's yearly income.

This table shows what our query result should be like:

	Internet Sales Amount	Yearly Income
Nichole Nara	\$13,295.38	100000 – 120000
Kaitlyn J. Henderson	\$13,294.27	100000 – 120000
Margaret He	\$13,269.27	100000 – 120000
Randall M. Dominguez	\$13,265.99	80000 – 90000
Adriana L. Gonzalez	\$13,242.70	80000 – 90000
Rosa K. Hu	\$13,215.65	40000 – 70000
Brandi D. Gill	\$13,195.64	100000 – 120000
Brad She	\$13,173.19	80000 – 90000
Francisco A. Sara	\$13,164.64	40000 – 70000
Maurice M. Shan	\$12,909.67	80000 – 90000

Once we get only the top 10 customers, it is easy enough to place the customer on the rows, and the Internet sales amount on the columns. What about each customer's yearly income?

The Customer Geography is a user-defined hierarchy in the Customer dimension. In SSMS, if you start a new query against the Adventure Works DW 2016 database, and navigate to **Customer | Customer Geography | Customer | Member Properties**, you will see that the yearly income is one of the member properties for the Customer attribute. This is good news, because now we can surely get the **Yearly Income** for each top 10 customer using the **Properties()** function:

How to do it...

In SSMS, let us write the following query in a new Query Editor against the Adventure Works DW 2016 database:

1. This query uses the `TopCount()` function, which takes three parameters. The first parameter `[Customer].[Customer Geography].[Customer].MEMBERS` provides the members that will be evaluated for the *top count*, the second integer, 10, tells it to return only ten members and the third parameter, `[Measures].[Internet Sales Amount]`, provides a numeric measure as the evaluation criterion:

```
-- Properties(): Initial
SELECT
    [Measures].[Internet Sales Amount] ON 0,
    TopCount(
        [Customer].[Customer Geography].[Customer].MEMBERS,
        10,
        [Measures].[Internet Sales Amount]
    ) ON 1
FROM
    [Adventure Works]
```

2. Execute the preceding query and we should get only ten customers back with their Internet Sales Amount. Also notice that the result is sorted in descending order of the numeric measure. Now let's add a calculated measure, like this:

```
[Customer].[Customer Geography].currentmember.Properties("Yearly
Income")
```

3. To make the calculated measure *dynamic*, we must use a member function `.currentMember`, so we do not need to hardcode any specific member name on the customer dimension. The `Properties()` function is also a member function, and it takes another attribute name as a parameter. We have provided `Yearly Income` as the name for the attribute we are interested in.
4. Now place the preceding expression in the `WITH` clause, and give it a name, `[Measures].[Yearly Income]`. This new calculated measure is now ready to be placed on the columns axis, along with the Internet Sales Amount. Here is the final query:

```
WITH
MEMBER [Measures].[Yearly Income] AS
```

```
[Customer].[Customer Geography].currentmember  
.Properties("Yearly Income")  
  
SELECT  
    { [Measures].[Internet Sales Amount],  
      [Measures].[Yearly Income]  
    } ON 0,  
TopCount(  
    [Customer].[Customer Geography].[Customer].MEMBERS,  
    10,  
    [Measures].[Internet Sales Amount]  
  ) ON 1  
FROM  
    [Adventure Works]
```

5. Executing the query, we should get the yearly income for each top 10 customer. The result should be exactly the same as the table shown at the beginning of our recipe.

How it works...

Attributes correspond to columns in the dimension tables in our data warehouse. Although we do not normally define the relationship between them in the relationship database, we do so in the multidimensional space. This knowledge of attribute relationships can be used by the Analysis Services engine to optimize the performance. MDX has provided us the `Properties()` function to allow us to get from members of one attribute to members of another attribute.

In this recipe, we only focus on one type of member property, that is, the user-defined member property. Member properties can also be the member properties that are defined by Analysis Services itself, such as `NAME`, `ID`, `KEY`, or `CAPTION`; they are the intrinsic member properties.

There's more...

The `Properties()` function can take another optional parameter, that is the `TYPED` flag. When the `TYPED` flag is used, the return value has the original type of the member.

The preceding example does not use the `TYPED` flag. Without the `TYPED` flag, the return value is always a string.

In most business analysis, we perform arithmetical operations numerically. In the next example, we will include the `TYPED` flag in the `Properties()` function to make sure that the `[Total Children]` for the top 10 customers are numeric:

```
WITH
MEMBER [Measures].[Yearly Income] AS
    [Customer].[Customer Geography].currentmember.Properties("Yearly
Income")
MEMBER [Measures].[Total Children] AS
    [Customer].[Customer Geography].currentmember.Properties("Total
Children", TYPED)
MEMBER [Measures].[Is Numeric] AS
    IIF(
        IsNumeric([Measures].[Total Children]),
        1,
        NULL
    )

SELECT
    { [Measures].[Internet Sales Amount],
      [Measures].[Yearly Income],
      [Measures].[Total Children],
      [Measures].[Is Numeric]
    } ON 0,
    TopCount(
        [Customer].[Customer Geography].[Customer].MEMBERS,
        10,
        [Measures].[Internet Sales Amount]
    ) ON 1
FROM
    [Adventure Works]
```

The following is the result:

	Internet Sales Amount	Yearly Income	Total Children	Is Numeric
Nichole Nara	\$13,295.38	100000 - 120000	2	1
Kaitlyn J. Henderson	\$13,294.27	100000 - 120000	3	1
Margaret He	\$13,269.27	100000 - 120000	3	1
Randall M. Dominguez	\$13,265.99	80000 - 90000	2	1
Adriana L. Gonzalez	\$13,242.70	80000 - 90000	5	1
Rosa K. Hu	\$13,215.65	40000 - 70000	5	1
Brandi D. Gill	\$13,195.64	100000 - 120000	2	1
Brad She	\$13,173.19	80000 - 90000	4	1
Francisco A. Sara	\$13,164.64	40000 - 70000	5	1
Maurice M. Shan	\$12,909.67	80000 - 90000	5	1

Attributes can be simply referenced as an attribute hierarchy, that is, when the attribute is enabled as an **Attribute Hierarchy**.

In SSAS, there is one situation where the attribute relationship can be explored only by using the `Properties()` function, that is when its `AttributeHierarchyEnabled` property is set to `False`.

In the employee dimension in the Adventure Works cube, employees' SSN numbers are not enabled as an Attribute Hierarchy. Its `AttributeHierarchyEnabled` property is set to `False`. We can only reference the SSN number in the `Properties()` function of another attribute that has been enabled as Attribute Hierarchy, such as the `Employee` attribute.

Basic sorting and ranking

Sorting and ranking are very common requirements in business analysis, and MDX provides several functions for this purpose. They are:

- `TopCount` and `BottomCount`
- `TopPercent` and `BottomPercent`
- * `TopSum` and `BottomSum`
- `ORDER`
- `Hierarchize`
- `RANK`

All of these functions operate on sets of tuples, not just on one-dimensional sets of members. They all, in some way, involve a numeric expression, which is used to evaluate the sorting and the ranking.

Getting ready

We will start with the classic top five (or top-n) example using the `TopCount()` function. We will then examine how the result is already pre-sorted, followed by using the `ORDER()` function to sort the result explicitly. Finally, we will see how we can add a ranking number by using the `RANK()` function.

Here is the classic top five example using the `TopCount()` function:

```
TopCount (
    [Product].[Subcategory].children,
    5,
    [Measures].[Internet Sales Amount]
)
```

It operates on a tuple; (`[Product].[Subcategory].children, [Measures].[Internet Sales Amount]`).

The result is the five `[Subcategory]` that have the highest `[Internet Sales Amount]`.

The five subcategory members will be returned in order from the largest `[Internet Sales Amount]` to the smallest.

How to do it...

In SSMS, let us write the following query in a new Query Editor, against the Adventure Works DW 2016 database. Follow these steps to first get the top-n members:

1. We simply place the earlier `TopCount()` expression on the rows axis.
2. On the columns axis, we are showing the actual `Internet Sales Amount` for each product subcategory.
3. In the slicer, we use a tuple to slice the result for the year 2013 and the Southwest only.

4. The final query should look like the following query:

```
SELECT
    [Measures].[Internet Sales Amount] ON 0,
    TopCount (
        [Product].[Subcategory].children,
        5,
        [Measures].[Internet Sales Amount]
    ) ON 1
FROM
    [Adventure Works]
WHERE
    ( [Date].[Calendar].[Calendar Quarter].&[2013]&[1],
        [Sales Territory].[Sales Territory Region].[Southwest]
    )
```

5. Run the query. The following screenshot shows the top-n result:

	Internet Sales Amount
Mountain Bikes	\$261,459.11
Road Bikes	\$138,047.52
Touring Bikes	\$99,980.73
Tires and Tubes	\$8,184.57
Helmets	\$7,277.92

6. Notice that the returned members are in order from the largest numeric measure to the smallest.

Next, in SSMS, follow these steps to explicitly sort the result:

1. This time, we will put the `TopCount()` expression in the `WITH` clause, creating it as a Named Set. We will name it `[Top 5 Subcategory]`.
2. On the rows axis, we will use the `ORDER()` function, which takes two parameters: which members we want to return and what value we want to evaluate on for sorting. The named set `[Top 5 Subcategory]` is what we want to return, so we will pass it to the `ORDER()` function as the first parameter. The `.MemberValue` function gives us the product subcategory name, so we will pass it to the `ORDER()` function as the second parameter. Here is the `ORDER()` function expression we would use:

```
ORDER (
    [Top 5 Subcategory],
    [Product].[Subcategory].MEMBERVALUE
)
Here is the final query for sorting the result:
-- Order members with MemberValue
WITH
SET [Top 5 Subcategory] as
    TopCount (
        [Product].[Subcategory].CHILDREN,
        5,
        [Measures].[Internet Sales Amount]
    )

SELECT
    [Measures].[Internet Sales Amount] on 0,
    ORDER (
        [Top 5 Subcategory],
        [Product].[Subcategory].MEMBERVALUE
    ) ON 1
FROM
    [Adventure Works]
WHERE
    ( [Date].[Calendar].[Calendar Quarter]&[2013]&[1],
    [Sales Territory].[Sales Territory
    Region].[Southwest] )
```

3. Executing the preceding query, we get the sorted result as the screenshot shows:

	Internet Sales Amount
Helmets	\$7,277.92
Mountain Bikes	\$261,459.11
Road Bikes	\$138,047.52
Tires and Tubes	\$8,184.57
Touring Bikes	\$99,980.73

Finally, in SSMS, follow these steps to add ranking numbers to the top-n result:

1. We will create a new calculated measure, [Subcategory Rank] using the RANK() function, which is simply putting a one-based ordinal position of each tuple in the set, [Top 5 Subcategory]. Since the set is already ordered, the ordinal position of the tuple will give us the correct ranking. Here is the expression for the RANK() function:

```
RANK (
    [Product].[Subcategory].CurrentMember,
    [Top 5 Subcategory]
)
```

2. The following query is the final query. It is built on top of the first query in this recipe. We have added the earlier RANK() function and created a calculated measure [Measures].[Subcategory Rank], which is placed on the columns axis along with the Internet Sales Amount:

```
WITH
SET [Top 5 Subcategory] AS
    TopCount (
        [Product].[Subcategory].children,
        5,
        [Measures].[Internet Sales Amount]
    )
MEMBER [Measures].[Subcategory Rank] AS
    RANK (
        [Product].[Subcategory].CurrentMember,
        [Top 5 Subcategory]
    )

SELECT
    { [Measures].[Internet Sales Amount],
        [Measures].[Subcategory Rank]
    } ON 0,
    [Top 5 Subcategory] ON 1
FROM
    [Adventure Works]
WHERE
    ( [Date].[Calendar].[Calendar Quarter].&[2013]&[1],
        [Sales Territory].[Sales Territory Region].[Southwest] )
```

3. Run the preceding query. The ranking result is shown in the following screenshot:

	Internet Sales Amount	Subcategory Rank
Mountain Bikes	\$261,459.11	1
Road Bikes	\$138,047.52	2
Touring Bikes	\$99,980.73	3
Tires and Tubes	\$8,184.57	4
Helmets	\$7,277.92	5

How it works...

Sorting functions, such as `TopCount()`, `TopPercent()`, and `TopSum()`, operate on sets of tuples. These tuples are evaluated on a numeric expression and returned pre-sorted in the order of a numeric expression.

Using the `ORDER()` function, we can sort members from dimensions explicitly using the `.MemberValue` function.

When a numeric expression is not specified, the `RANK()` function can simply be used to display the one-based ordinal position of tuples in a set.

There's more...

Like the other MDX sorting functions, the `RANK()` function, however, can also operate on a numeric expression. If a numeric expression is specified, the `RANK()` function assigns the same rank to tuples with duplicate values in the set.

It is also important to understand that the `RANK()` function does not order the set. Because of this fact, we tend to do the ordering and ranking at the same time. However, in the last query of this recipe, we actually used the `ORDER()` function to first order the set of members of the subcategory. This way, the sorting is done only once and then followed by a linear scan, before being presented in sorted order.

As a good practice, we recommend using the `ORDER()` function to first order the set and then ranking the tuples that are already sorted.

Handling division by zero errors

Handling errors is a common task, especially the handling of division by zero type errors. This recipe offers a common practice to handle them.

Getting ready

Start a new query in SQL Server Management Studio and check that you're working on the Adventure Works database. Then write and execute this query:

```
WITH
MEMBER [Date].[Calendar Year].[CY 2012 vs 2011 Bad] AS
    [Date].[Calendar Year].[Calendar Year].&[2012] /
    [Date].[Calendar Year].[Calendar Year].&[2011],
    FORMAT_STRING = 'Percent'
SELECT
    { [Date].[Calendar Year].[Calendar Year].&[2012],
        [Date].[Calendar Year].[Calendar Year].&[2011],
        [Date].[Calendar Year].[CY 2012 vs 2011 Bad] } *
    [Measures].[Reseller Sales Amount] ON 0,
    { [Sales Territory].[Sales Territory].[Country].MEMBERS }
ON 1
FROM
    [Adventure Works]
```

This query returns six countries on the rows axis, and two years and a ratio on the column axis:

	CY 2012	CY 2011	CY 2012 vs 2011 Bad
	Reseller Sales Amount	Reseller Sales Amount	Reseller Sales Amount
France	\$1,385,989.49	\$97,496.29	1421.58%
Germany	\$180,040.57	(null)	1.#INF
United Kingdom	\$1,478,289.76	\$80,686.69	1832.14%
Canada	\$5,478,100.19	\$3,602,561.12	152.06%
United States	\$19,621,386.81	\$14,412,058.61	136.15%
Australia	\$49,824.71	(null)	1.#INF

The problem is that we get **1.#INF** on some ratio cells. **1.#INF** is the formatted value of infinity, and it appears whenever the denominator **CY 2011** is null and the nominator **CY 2012** is not null.

We will need help from the **IIF()** function, which takes three arguments:

IFF(<condition>, <then branch>, <else branch>). The **IIF()** function is a **Visual Basic for Applications (VBA)** function and has a native implementation in MDX. The **IIF()** function will allow us to evaluate the condition of **CY 2011**, then decide what the ratio calculation formula should be.

How to do it...

Follow these steps to handle division by zero errors:

1. Copy the calculated member and paste it as another calculated member. During that, replace the term **Bad** with **Good** in its name, just to differentiate between those two members.
2. Copy the denominator.
3. Wrap the expression in an outer **IIF()** statement.
4. Paste the denominator in the condition part of the **IIF()** statement and compare it against 0.
5. Provide null value for the true part.
6. Your initial expression should be in the false part.
7. Don't forget to include the new member on columns and execute the query:

```
WITH
MEMBER [Date].[Calendar Year].[CY 2012 vs 2011 Bad] AS
    [Date].[Calendar Year].[Calendar Year].&[2012] /
    [Date].[Calendar Year].[Calendar Year].&[2011],
    FORMAT_STRING = 'Percent'
MEMBER [Date].[Calendar Year].[CY 2012 vs 2011 Good] AS
    IIF([Date].[Calendar Year].[Calendar Year].&[2011] = 0,
        null,
        [Date].[Calendar Year].[Calendar Year].&[2012] /
        [Date].[Calendar Year].[Calendar Year].&[2011]
    ),
    FORMAT_STRING = 'Percent'
SELECT
{ [Date].[Calendar Year].[Calendar Year].&[2011],
  [Date].[Calendar Year].[Calendar Year].&[2012],
  [Date].[Calendar Year].[CY 2012 vs 2011 Bad],
  [Date].[Calendar Year].[CY 2012 vs 2011 Good] } *
```

```
[Measures].[Reseller Sales Amount] ON 0,
{ [Sales Territory].[Sales Territory].[Country].MEMBERS }
ON 1
FROM
[Adventure Works]
```

The result shows that the new calculated measure has corrected the problem. The last column [**CY 2012 vs 2011 Good**] is now showing (null) correctly when the denominator **CY 2011** is null and the nominator **CY 2012** is not null.

	CY 2012	CY 2011	CY 2012 vs 2011 Bad	CY 2012 vs 2011 Good
	Reseller Sales Amount	Reseller Sales Amount	Reseller Sales Amount	Reseller Sales Amount
France	\$1,385,989.49	\$97,496.29	1421.58%	1421.58%
Germany	\$180,040.57	(null)	1.#INF	(null)
United Kingdom	\$1,478,289.76	\$80,686.69	1832.14%	1832.14%
Canada	\$5,478,100.19	\$3,602,561.12	152.06%	152.06%
United States	\$19,621,386.81	\$14,412,058.61	136.15%	136.15%
Australia	\$49,824.71	(null)	1.#INF	(null)

How it works...

A division by zero error occurs when the denominator is null or zero and the numerator is not null. In order to prevent this error, we must test the denominator before the division and handle the two scenarios in the two branches using the **IIF()** statement.

In the condition part of the IIF statement, we've used a simple scalar number zero to determine whether **[Measures].[Reseller Sales Amount]** in the following slicer is zero or not. If it is zero, then it will be true and the calculated member will be NULL:

```
[Date].[Calendar Year].[Calendar Year]&[2011] = 0
```

What about the NULL condition? It turned out for a numerical value; we do not need to test the NULL condition specifically. It is enough to test just for zero because **null = 0** returns true. However, we could test for a NULL condition if we want to, by using the **IsEmpty()** function.

For the calculated member, [CY 2012 vs 2011 Good] we could wrap the member with the `IsEmpty()` function. The result will be the same:

```
MEMBER [Date].[Calendar Year].[CY 2012 vs 2011 Good] AS  
    IIF(IsEmpty([Date].[Calendar Year].[Calendar Year].&[2011]),  
        null,  
        [Date].[Calendar Year].[Calendar Year].&[2012] /  
        [Date].[Calendar Year].[Calendar Year].&[2011]  
    ),  
    FORMAT_STRING = 'Percent'
```

There's more...

SQLCAT's SQL Server 2008 Analysis Services Performance Guide has a lot of interesting details regarding the `IIF()` function, found at <http://tinyurl.com/PerfGuide2008R2>.

Additionally, you may find the blog article *MDX and DAX topics* by Jeffrey Wang, explaining the details of the `IIF()` function, found at <http://tinyurl.com/IIFJeffrey>.

Earlier versions of SSAS

If you're using a version of SSAS prior to 2008 (that is, 2005), the performance of the `IIF()` function will not be as good. See Mosha Pasumansky's article for more information: <http://tinyurl.com/IIFMosha>.

Setting a default member of a hierarchy in the MDX script

Setting a default member is a tempting option which looks like it can be used on any dimension we would like. The truth is far from that. Default members should be used as exceptions and not as a general rule when designing dimensions.

The reason for that is not so obvious. The feature looks self-explanatory, and it is hard to anticipate what could go wrong. If we are not careful enough, our calculations can become unpredictable, especially on complex dimensions with many relationships among attributes.

Default members can be defined in three places. The easy-to-find option is the dimension itself, using the `DefaultMember` property found on every attribute. The second option is the role, on the **Dimension Data** tab. Finally, default members can be defined in the MDX script. One of the main benefits of this place is easy maintenance of all default members in the cube because everything is in one place, and in the form of easy-to-read text. That is also the only way to define the default member of a role-playing dimension.

In this recipe, we will show the most common option, that is, the last one, or how to set a default member of a hierarchy in the MDX script. More information on setting the `DefaultMember` is available at <http://tinyurl.com/DefaultMember2012>.

Getting ready

Follow these steps to set up the environment for this recipe:

1. Start SSMS and connect to your SSAS 2016 instance.
2. Click on the **New Query** button and check that the target database is Adventure Works DW 2016. Then execute the following query:

```
WITH
MEMBER [Measures].[Default account] AS
    [Account].[Accounts].DefaultMember.Name
SELECT
    { [Measures].[Amount],
      [Measures].[Default account] } ON 0
FROM
    [Adventure Works]
```

3. The results will show that the default member is the **Net Income** account and its value in this context is a bit more than 12.6 million USD.
4. Next, open Adventure Works DW 2016 solution in SSDT.
5. Double-click on the Adventure Works cube and go to the **Calculations** tab. Choose **Script View**.
6. Position the cursor at the beginning of the script, just beneath the **CALCULATE** command.

How to do it...

Follow these steps to set a new default member:

1. Enter the following expression to set a new default account:

```
ALTER CUBE CurrentCube  
    UPDATE DIMENSION [Account].[Accounts],  
        Default_Member = [Account].[Accounts].&[48];  
        //Operating Profit
```

2. Save and deploy (or just press the **Deploy MDX Script** icon if you're using BIDS Helper 2012 or 2016 Preview version).
3. Run the previous query again.
4. Notice that the result has changed. The new default account is Operating Profit, the one we specified in the MDX script using the `ALTER CUBE` command. The value changed as well now: it's above 16.7 million USD:

Amount	Default account
\$16,728,234.50	Operating Profit

How it works...

The `ALTER CUBE` statement changes the default member of a hierarchy specified in the `UPDATE DIMENSION` part of the statement. The third part is where we specify which member should be the default member of that hierarchy.

Don't mind that it says `UPDATE DIMENSION`. SSAS 2016 interprets that as a hierarchy.

There's more...

Setting the default member on a dimension with multiple hierarchies can lead to unexpected results. Due to attribute relations, related attributes are implicitly set to corresponding members, while the non-related attributes remain on their default members, that is, the *All* member (also known as the root member). Certain combinations of members from all available hierarchies can result in a non-existing coordinate. In that case, the query will return no data. Other times, the intersection will only be partial. In that case, the query will return the data, but the values will not be correct, which might be even worse than no data at all.

Enter the following expression in the MDX script, then deploy it:

```
ALTER CUBE CurrentCube
    UPDATE DIMENSION [Date].[Calendar],
        Default_Member = [Date].[Calendar]
            .[Calendar Year].&[2012];
            -- year 2012 on the user hierarchy
```

The expression sets the year 2012 as the default member of the [Date].[Calendar] user-defined hierarchy.

Let's analyze the result with the following query:

```
SELECT
    [Measures].[Sales Amount] ON 0,
    [Date].[Fiscal].[Fiscal Year] ON 1
FROM
    [Adventure Works]
```

The result is shown in the following screenshot:

	Sales Amount
FY 2005	(null)
FY 2006	(null)
FY 2007	(null)
FY 2008	(null)
FY 2009	(null)
FY 2010	(null)
FY 2011	\$17,535,490.47
FY 2012	\$16,500,626.26
FY 2013	(null)
FY 2014	(null)

The analysis of the Sales Amount measure for each fiscal year returns empty results except in **FY 2011** and **FY 2012**. They are empty because the intersection between the fiscal year and the calendar year 2012 (the latter being the default member in the calendar hierarchy) is a non-existing combination, except **FY 2011** and **FY 2012**. Remember, the calendar year 2012 doesn't get overwritten by the fiscal year 2011 or 2012. It gets combined (open the Date dimension in SSDT and observe the relationships in the corresponding tab). Moreover, when you put the fiscal year 2011 or 2012 into the slicer, you only get a portion of data; the portion which matches the intersection of the calendar and the fiscal year. That's only one half of the fiscal year, right? In short, you have a potential problem with this approach.

Can we fix the result? Yes, we can. The correct results will be there when we explicitly select the *All* member from the Date.Calendar hierarchy in the slicer. The complete MDX is shown in the following query. Only then will we get correct results using fiscal hierarchies. The question is—will the end users remember that every time?

```
SELECT [Measures].[Sales Amount] ON 0,  
       [Date].[Calendar Year].[All] *  
       [Date].[Fiscal].[Fiscal Year] ON 1  
FROM  
     [Adventure Works]
```

The correct results from this query can be seen in the following screenshot:

		Sales Amount
All Periods	FY 2005	(null)
All Periods	FY 2006	(null)
All Periods	FY 2007	(null)
All Periods	FY 2008	(null)
All Periods	FY 2009	(null)
All Periods	FY 2010	\$10,799,059.35
All Periods	FY 2011	\$32,537,509.38
All Periods	FY 2012	\$42,352,684.66
All Periods	FY 2013	\$24,120,020.81
All Periods	FY 2014	(null)

The situation is similar when the default member is defined on an attribute hierarchy, for example, on the [Date]. [Calendar Year] hierarchy. By now, you should be able to modify the previous expression so that it sets the year 2012 as the default member on the [Date]. [Calendar Year]. Test this to see it for yourself.

Another scenario could be that you want to put the current date as the default member on the Date.Date hierarchy. Try that too, and see that when you use the year 2012 from the [Date]. [Calendar Year] hierarchy in the slicer, you get an empty result. Again, the intersection formed a non-existing coordinate.

To conclude, you should avoid defining default members on complex dimensions. Define them where it is appropriate: on dimensions with a single non-aggregatable attribute (that is, when you set the `IsAggregatable` property of an attribute to `False`) or on dimensions with one or more user hierarchies where that non-aggregatable attribute is the top level on each user hierarchy, and where all relationships are well defined.

The Account dimension used in this example is not such a dimension. In order to correct it, two visible attributes should be hidden because they can cause empty results when used in a slicer. Experimenting with a scope might help too, but that adds to the complexity of the solution and hence the initial advice of keeping things simple when using default members should prevail.

Take a look at other dimensions in the Adventure Works DW 2016 database. There, you will find good examples of using default members.

Helpful tips

When you're defining the default members in an MDX script, do it at the beginning of the script. This way, the calculations that follow can reference them.

In addition, provide a comment explaining which member was chosen to be the default member, and perhaps why. Look back at the code in this recipe to see how it was done.

2

Working with Sets

In this chapter, we will cover the following recipes:

- Implementing the NOT IN set logic
- Implementing the logical OR on members from different hierarchies
- Iterating on a set to reduce it
- Iterating on a set to create a new one
- Iterating on a set using recursion
- Performing complex sorts
- Dissecting and debugging MDX queries
- Implementing the logical AND on members from the same hierarchy

Introduction

Sets in MDX are collections of tuples with the same dimensionality. As in many other programming languages, the basic logical operations, NOT, AND, and OR, can be applied on them.

When putting two tuples together to form a set, we basically ask for the results that contain any of those tuples. Therefore, sets in MDX naturally imply the OR logic. The first part of the chapter focuses on the challenges and solutions of performing NOT and OR logic operations on sets.

Iterations and recursions can also be performed on sets. The middle part of the chapter concentrates on those actions and the different ways to perform them.

The final part of the chapter explains how to perform complex sorts, how to apply the iteration technique to dissect and debug MDX queries and calculations, and how to perform the logical AND operation in MDX.

Implementing the NOT IN set logic

There are times when we want to exclude some members from the result. We can perform this operation using a set of members on an axis or using a set of members in a slicer, that is, the WHERE part of an MDX query.

This recipe shows how to do the latter, that is, how to exclude some members from a set in a slicer. The principle is the same for any part of an MDX query.

Getting ready

Start a new query in SQL Server Management Studio (SSMS) and check that you are working on the Adventure Works DW 2016 database. Then type in the following query and execute it:

```
SELECT
    { [Measures].[Reseller Order Count] } ON 0,
    NON EMPTY
    { [Promotion].[Promotion].MEMBERS }
    DIMENSION PROPERTIES
        [Promotion].[Promotion].[Discount Percent]
    ON 1
FROM
    [Adventure Works]
```

The preceding query returns 12 promotions and all the top-level promotions on the rows axis. The DIMENSION PROPERTIES keyword is used to get additional information about members each promotion's discount percent. However, the property is not visible on either of the query axes and it can only be seen by double-clicking each promotion member on the rows:

	Reseller Order Count
All Promotions	3,796
No Discount	3,782
Volume Discount 11 to 14	570
Volume Discount 15 to 24	347
Volume Discount 25 to 40	71
Volume Discount 41 to 60	2
Mountain-100 Clearance Sale	24
Sport Helmet Discount-2002	36
Road-650 Overstock	61
Sport Helmet Discount-2003	30
Touring-3000 Promotion	101
Touring-1000 Promotion	101
Mountain-500 Silver Clearance Sale	62

Our task is to exclude promotions with a discount percentage of 0, 2, and 5.

How to do it...

To exclude promotions with a discount percent of 0, 2, and 5 is to say that we want the promotion members that are NOT IN the discount percent (0, 2, and 5). Translating the NOT IN logic into the WHERE clause, we can use this pseudo code:

```
WHERE
( - { [member of Discount Percent 0],
      [member of Discount Percent 2],
      [member of Discount Percent 5] } )
```

All we need to do now is to find the three fully qualified member names.

Let us open a new query in SSMS against the Adventure Works DW 2016 database, and follow these steps:

1. Navigate to the `Promotion` dimension and expand it.
2. Expand the `Discount Percent` hierarchy and its level.
3. Take the first three members (with the names 0, 2, and 5) and drag them one by one beneath the query, and then form a set of them using curly brackets.

4. Expand the query by adding the WHERE part.
5. Add the set with those three members using a minus sign in front of the set:

```
SELECT
{ [Measures].[Reseller Order Count] } ON 0,
NON EMPTY
{ [Promotion].[Promotion].MEMBERS }
DIMENSION PROPERTIES
    [Promotion].[Promotion].[Discount Percent]
ON 1
FROM
    [Adventure Works]
WHERE
( - { [Promotion].[Discount Percent].&[0],
[Promotion].[Discount Percent].&[2.E-2],
[Promotion].[Discount Percent].&[5.E-2] } )
```

6. Execute the query and see how the results change. Double-click each promotion and verify that no promotion has a discount percent equal to 0, 2, or anymore.

How it works...

The initial query is not sliced by discount percentages. We can think of it as if all the members of that hierarchy exist there in the slicer:

```
WHERE ( { [Promotion].[Discount Percent]
    .[Discount Percent].MEMBERS } )
```

Of course, we don't have to write such expressions; the SSAS engine takes care of it by default. In other words, we're fine until the moment we want to change the slicer by either isolating or removing some members from that set. That's when we have to use that hierarchy in the slicer.

Isolation of members is simply done by enumerating them in the slicer. Reduction, the opposite operation, is performed using the Except() function:

```
WHERE ( Except( { [Promotion].[Discount Percent]
    .[Discount Percent].MEMBERS },
{ [Promotion].[Discount Percent].&[0],
[Promotion].[Discount Percent].&[2.E-2],
[Promotion].[Discount Percent].&[5.E-2] }
)
)
```

The alternative for the `Except ()` function is a minus sign, which brings us to the shorter version of the previous expression, the version that was used in this recipe.

Notice that the `Except ()` function takes two sets, and the minus sign in our example has only one set after it, and has no set before it.

When a minus sign is used between two sets, it performs the same difference operation between those sets as `Except ()` does. When the first set is missing, which is the case in our example, all the members of the second set are implicitly added as the first set. The difference between all members and the members of any set is the opposite set of that set. This is how you can perform the `NOT IN` logic on sets. Both variants work, but the one with the minus sign in front of the set is hopefully easier to remember.

There's more...

If we open the `Promotion` dimension inside SQL Server Data Tools (SSDT), we'll notice that the `Discount Percent` attribute has the `MemberValue` property defined. The value of that property is equal to a discount percentage and therefore, in this case, we could write an equivalent syntax:

```
WHERE
  ( { Filter( [Promotion].[Discount Percent]
              .[Discount Percent].MEMBERS,
              [Promotion].[Discount Percent]
              .CurrentMember.MemberValue >= 0.1 ) } )
```

The advantage of this expression is that it should filter out additional members with a percentage less than 10 percent, if they ever appear on that hierarchy. If we're not expecting such a case or if we strictly want to exclude certain, not necessarily consecutive, members from the hierarchy (Unknown Member, NA member, and so on), we should use the first example: the one with explicit members in the set.

See also

- The next recipe, *Implementing the logical OR on members from different hierarchies* is based on a similar theme to this recipe

Implementing the logical OR on members from different hierarchies

If we need to slice the data by only the black color for products, we would put the Black member in the WHERE clause, like this:

```
WHERE  
( [Product].[Color].&[Black] )
```

In the Adventure Works DW 2016 database, by putting **Reseller Order Quantity** and **Reseller Order Count** on the columns, we would get this result:

	Reseller Order Quantity	Reseller Order Count
All Products	72,013	2,970
Cranksets	1,107	261
Gloves	11,553	991
Helmets	4,447	922
Mountain Bikes	12,771	1,119
Mountain Frames	5,604	736
Road Bikes	14,304	1,237
Road Frames	3,456	769
Shorts	8,946	758
Tights	4,562	470
Wheels	5,263	716

Similarly, to get only the products whose size is XL, we can put the member XL in the slicer as:

```
WHERE  
( [Product].[Size Range].&[XL] )
```

What if we want to get the products whose size is XL in the same result set as the result set for black only?

Somehow, we need to combine the black member with the XL member. Simply by putting these two members together, it would not work. Putting two members from different hierarchies would form a tuple; a tuple implies the logical AND in MDX, not the logical OR.

On the other hand, MDX implies a logical **OR**. However, we cannot simply put the preceding two members together to form a set. **Color** and **Size Range** are different hierarchies. Yes, they belong to the same **Product** dimension, but only items from the same hierarchy, not dimension, can form a set!

In this recipe, we will focus on how to implement a logical **OR** on members from different hierarchies.

Getting ready

Start a new query in SSMS and check that you're working on the Adventure Works DW 2016 database. We will start with slicing by the black color first. Type in the following query and execute it:

```
SELECT
    { [Measures].[Reseller Order Quantity],
      [Measures].[Reseller Order Count] } ON 0,
    NON EMPTY
    { [Product].[Subcategory].MEMBERS } ON 1
FROM
    [Adventure Works]
WHERE
    ( [Product].[Color].&[Black] )
```

The query displays 10 product subcategories containing all the black products, plus one row on the top level [**All Products**].

Next, open a new query window and execute the following query:

```
SELECT
    { [Measures].[Reseller Order Quantity],
      [Measures].[Reseller Order Count] } ON 0,
    NON EMPTY
    { [Product].[Subcategory].MEMBERS } ON 1
FROM
    [Adventure Works]
WHERE
    ( [Product].[Size Range].&[XL] )
```

It is a query like the previous one, but this one returns only product subcategories containing XL size range products. There's only one product subcategory in the result, **Jerseys**.

Our task is to combine these queries so that we get the result of the OR operation on those two conditions, in a single query, of course.

How to do it...

Our goal is to combine these two members from different hierarchies and place them in the slicer:

```
[Product].[Color].&[Black]  
[Product].[Size Range].&[XL]
```

To combine members from different hierarchies, we need to make sure that they have the same dimensionality. Here is our solution:

1. We need to form two tuples that have the same dimensionality and then combine the two tuples with the same dimensionality to form a set. To form two tuples that have the same dimensionality, we add one more member expression, [Product].[Size Range].[All Products], to each member, separating each member by a comma, and enclosing the tuple with a pair of parentheses. The pair of curly brackets indicates a set; each tuple in the set is separated by a comma; the member order in each tuple must be the same:

```
WHERE  
(  
    { ( [Product].[Color].&[Black],  
        [Product].[Size Range].[All Products] )  
  
    ,  
    ( [Product].[Color].[All Products],  
        [Product].[Size Range].&[XL] ) }  
)
```

2. Here is the final query:

```
SELECT  
    { [Measures].[Reseller Order Quantity],  
      [Measures].[Reseller Order Count] } ON 0,  
    NON EMPTY  
    { [Product].[Subcategory].MEMBERS } ON 1  
FROM  
    [Adventure Works]  
WHERE  
(  
    { ( [Product].[Color].&[Black],  
        [Product].[Size Range].[All Products] )  
  
    ,  
    ( [Product].[Color].[All Products],  
        [Product].[Size Range].&[XL] ) } ON 0)
```

```
( [Product].[Color].[All Products],  
[Product].[Size Range].&[XL] )  
)
```

3. Executing the preceding query, we would get the result as shown in the following screenshot. **Jerseys** is the only product that is picked up by the XL size range. Notice that the cell values for **[All Products]** are also properly aggregated for all 12 products, including **Jerseys**:

	Reseller Order Quantity	Reseller Order Count
All Products	78,035	3,017
Cranksets	1,107	261
Gloves	11,553	991
Helmets	4,447	922
Jerseys	6,022	967
Mountain Bikes	12,771	1,119
Mountain Frames	5,604	736
Road Bikes	14,304	1,237
Road Frames	3,456	769
Shorts	8,946	758
Tights	4,562	470
Wheels	5,263	716

How it works...

The nature of a multidimensional database and its underlying structures has a direct consequence on how we should write the combinations of members. Some combinations are there by design, others require a bit of imagination.

For example, a set of two members of the same hierarchy (colors black and white) placed in a slicer automatically applies the **OR** logic on the result. This means that the result will have data where the first, the second, or both members (or at least one of their descendants, to be precise) occurred in the underlying fact table. In other words, where the product sold was either black or white. The emphasis is on two things: the set and the **OR** word. In other words, the **OR** logic manifests in sets.

The other example is a tuple formed by two members from different hierarchies (that is, the color black and size XL). Once placed in the slicer, this tuple guarantees that the resulting rows will have data on that exact slice, meaning, on both members (and at least one of the descendants of each, to be precise). Here, the emphasis is again on two things: the tuple and the AND word. In other words, the AND logic manifests in tuples.

Let's summarize. In MDX, a set is, by default, the equivalent of the logical OR while a tuple is, by default, the equivalent of the logical AND. So where's the problem?

The problem is we can only put members of different hierarchies in a tuple and of the same hierarchy in a set. Which means we're missing two combinations: different hierarchies using OR and the same hierarchy using AND.

This recipe shows how to implement the OR logic using members from different hierarchies. The next recipe in this chapter shows how to perform the AND logic using members from the same hierarchy. It is recommended that you read both recipes.

Logical OR represents a set. Since we have members of different dimensionalities, we must first convert them to tuples of the same dimensionality. That is done by expanding each with the other one's root member and enclosing the expression in brackets (which is how we convert a member to a tuple). Once we have compatible tuples, we can convert them into a set by separating them with a comma and adding curly brackets around the whole expression. This is the standard way that we enumerate members in single-dimensional sets. Multi-dimensional sets are no different except it's the tuples that we're enumerating this time.

There's more...

We can also use the `Union()` function instead of enumerating members in the set. The `Union()` function has an extra feature, an option to remove or preserve duplicates in the resulting set. While that feature is of little interest when the slicer is concerned, it might be interesting when the same logic is applied in calculations.

A special case of a non-aggregatable dimension

In the event that your dimension has no root member (eliminated by setting the property `IsAggregatable` to `False`), use its default member instead.

A very complex scenario

In this recipe, we used two hierarchies of the same dimension because this is often the case in real life. However, the solution is applicable to any dimension and its hierarchies. For example, when you need to combine three different hierarchies, you can apply the same solution, thereby expanding each member into a tuple with $N-1$ root members (here $N=2$) and creating a set of N such tuples.

In case you need to combine many members using OR logic, sometimes with even more than one of them on the same hierarchy and others on different hierarchies, you need to apply your knowledge about dimensionality—members of the same hierarchy should be enlisted in a set, and members of different dimensions should be combined with root members of other hierarchies. You just need to be careful with the various brackets. The `AsymmetricSet()` function from the Analysis Services Stored Procedure Project may help to construct complex sets: <http://tinyurl.com/AsymmetricSet>.

Iterating on a set to reduce it

Iteration is a very natural way of thinking for us humans. We set a starting point, we step into a loop, and we end when a condition is met. While we're looping, we can do whatever we want: check, take, leave, and modify items in that set.

In this recipe, we will start from a result set as shown in the following table, and iterate through the days in each fiscal month to count the number of days for which the growth was positive. By *to reduce*, we mean the filtering effect; in our example, we need to *filter out* the days for which the growth was not positive. Our goal is still to only display the fiscal months on ROWS, not the days:

	Customer Count	Growth in Customer Base
February 2013	152	-20.00%
March 2013	222	46.05%
April 2013	208	-6.31%
May 2013	260	25.00%
June 2013	350	34.62%
July 2013	293	-16.29%
August 2013	318	8.53%
September 2013	310	-2.52%
October 2013	351	13.23%
November 2013	397	13.11%
December 2013	421	6.05%
January 2014	(null)	-100.00%

Then we will look at a different approach that takes performance advantage of the block-mode calculation.

Getting ready

Start a new query in SSMS against the Adventure Works DW 2016 database. Then write the following query:

```
SELECT
    { [Measures].[Customer Count],
      [Measures].[Growth in Customer Base] } ON 0,
    NON EMPTY
    { [Date].[Fiscal].[Month].MEMBERS } ON 1
FROM
    [Adventure Works]
WHERE
    ( [Product].[Product Categories].[Subcategory].&[1] )
```

The query returns fiscal months on the rows and two measures: a count of customers, and their growth compared to the previous month. Mountain bikes are in the slicer. The first few rows from the result set are shown in the preceding table.

Now let us see how we can get the number of days the growth was positive for each period.

How to do it...

We are going to use the `Filter()` function to loop through the descendants of the fiscal month on `leaves`, and apply the `Count()` function to get the count of days. We will put the expression in the `WITH` clause and name it `[Measures].[Positive growth days]`. Finally, we will place this new calculated member on the columns:

1. The final query is as follows:

```
WITH
MEMBER [Measures].[Positive growth days] AS
    Filter(
        Descendants([Date].[Fiscal].CurrentMember, ,
                    leaves),
        [Measures].[Growth in Customer Base] > 0
            ).Count
SELECT
    { [Measures].[Customer Count],
      [Measures].[Growth in Customer Base],
      [Measures].[Positive growth days] } ON 0,
    NON EMPTY
    { [Date].[Fiscal].[Month].MEMBERS } ON 1
FROM
    [Adventure Works]
WHERE
    ( [Product].[Product Categories].[Subcategory].&[1] )
```

2. Run the preceding query and observe whether the results match the following screenshot:

	Customer Count	Growth in Customer Base	Positive growth days
July 2012	95	-13.64%	12
August 2012	114	20.00%	9
September 2012	105	-7.89%	12
October 2012	119	13.33%	13
November 2012	127	6.72%	9
December 2012	149	17.32%	14
January 2013	190	27.52%	14
February 2013	152	-20.00%	12
March 2013	222	46.05%	15
April 2013	208	-6.31%	14
May 2013	260	25.00%	15
June 2013	350	34.62%	12
July 2013	293	-16.29%	16
August 2013	318	8.53%	14
September 2013	310	-2.52%	13
October 2013	351	13.23%	12
November 2013	397	13.11%	12
December 2013	421	6.05%	14
January 2014	(null)	-100.00%	0

How it works...

Iteration is a technique that steps into a loop, checks or modifies items in the set, and then exits the loop when a condition is met.

Our goal is to count the number of days for which the growth was positive. Therefore, it might seem appropriate to perform iteration on days in each fiscal month. Iteration can be performed by using the `Filter()` function.

First, since we do not want to have the days on the rows, we must use the `Descendants()` function to get all dates in the current context.

Second, to get the number of items that came up when filtering, we use the `Count()` function.

Iteration works in this situation; however, if there's a way to manipulate the collection of members in block mode, without cutting that set into small pieces and iterating on individual members, we should use it.

There's more...

The `Filter()` function is an iterative function which doesn't run in block mode; hence, it will slow down the query.

Let us see if we can find a way to work in block mode. A keen eye will notice a *count of filtered items* pattern in this expression. That pattern suggests the use of a set-based approach in the form of a SUM-IF combination. The trick is to provide 1 for the true part of the condition taken from the `Filter()` statement and `null` for the false part. The sum of 1 will be equivalent to the count of filtered items.

This is the same `WITH` clause, being rewritten by using the SUM-IF combination:

```
WITH
MEMBER [Measures].[Positive growth days] AS
    Sum(
        Descendants( [Date].[Fiscal].CurrentMember, , leaves ),
        iif( [Measures].[Growth in Customer Base] > 0, 1, null )
    )
```

Execute the query using the new definition. Both the `Sum()` and the `iif()` functions are optimized to run in the block mode, especially when one of the branches in `iif()` is `null`. In this example, the impact on performance was not noticeable because the set of rows was relatively small. Applying this technique on large sets will result in drastic performance improvement as compared with the **FILTER-COUNT** approach.

More information about this type of optimization can be found in Mosha Pasumansky's blog, at <http://tinyurl.com/SumIIF>.

Hints for query improvements

There are several ways in which we can avoid the `Filter()` function to improve performance.

When you need to filter by non-numeric values (that is, properties or other metadata), you should consider creating an attribute hierarchy for often-searched items and then do one of the following:

- Use a tuple when you need to get a value sliced by that new member
- Use the `Except()` function when you need to negate that member on its own hierarchy (`NOT` or `<>`)
- Use the `Exists()` function when you need to limit other hierarchies of the same dimension by that member
- Use the `NonEmpty()` function when you need to operate on other dimensions, that is, subcubes created with that new member
- Use the three-argument `Exists()` function instead of the `NonEmpty()` function, if you also want to get combinations with nulls in the corresponding measure group (nulls are available only when the `NullProcessing` property for a measure is set to `Preserve`)

When you need to filter by values and then count a member in that set, you should consider aggregate functions such as `Sum()` with the `iif()` part in its expression, as described earlier.

- The next recipes, *Iterating on a set to create a new one* and *Iterating on a set using recursion*, deal with other methods of iteration

Iterating on a set to create a new one

There are situations when we don't want to eliminate certain members from a set, but instead execute for each type of loop. This is done using the `Generate()` function. The `Generate()` function applies a set to each member of another set, and then joins the resulting sets by union. In this recipe, we'll show you how to create a new set of members from the existing one.

Getting ready

Let's start a new query in SSMS against the Adventure Works DW 2016 database. Then write the following query:

```
SELECT
    NON EMPTY
    { [Date].[Calendar].[Calendar Year].MEMBERS *
      [Measures].[Sales Amount] } ON 0,
    NON EMPTY
    { [Sales Territory].[Sales Territory Country].MEMBERS }
    ON 1
FROM
    [Adventure Works]
```

The query returns four years on the columns and six countries plus the top level, **All Sales Territories**, on the rows. The result is shown as follows:

	CY 2010	CY 2011	CY 2012	CY 2013	CY 2014
	Sales Amount	Sales Amount	Sales Amount	Sales Amount	Sales Amount
All Sales Territories	\$532,749.62	\$25,268,328.64	\$34,036,116.73	\$49,926,384.50	\$45,694.72
Australia	\$20,909.78	\$2,563,732.25	\$2,178,232.17	\$5,883,954.04	\$8,507.72
Canada	\$118,939.17	\$4,174,132.92	\$5,785,704.71	\$6,267,536.04	\$9,457.62
France	\$3,399.99	\$508,341.62	\$2,034,055.03	\$4,702,563.95	\$3,195.06
Germany	(null)	\$520,500.16	\$788,698.55	\$3,565,823.83	\$3,277.83
United Kingdom	\$699.10	\$631,277.91	\$2,190,990.72	\$4,844,039.67	\$3,713.64
United States	\$388,801.58	\$16,870,343.78	\$21,058,435.54	\$24,662,466.97	\$17,542.85

Our goal is to get a set of best months, one for each year. We will use the `Generate()` function to do a `for-each` type of loop to apply a set of calendar months to each member of the calendar year, and to get the best month for each year.

How to do it...

Follow these steps to create a new set from the initial one:

1. Cut the years from the columns and define a named set using them.
2. Name that set `Best month per year`.

3. Wrap that set in the `Generate()` function so that the set of years becomes its first argument.
4. The second argument should be the `TopCount()` function which uses the descendants of each year on the Month level and finds the best month according to the value of the measure Sales Amount.
5. Put the name of the new set on columns.
6. The final query should look as follows:

```
WITH
SET [Best month per year] AS
    Generate( [Date].[Calendar].[Calendar Year].MEMBERS,
        TopCount(
            Descendants( [Date].[Calendar].CurrentMember,
                [Date].[Calendar].[Month],
                SELF ),
            1,
            [Measures].[Sales Amount] )
    )
SELECT
    NON EMPTY
    { [Best month per year] *
        [Measures].[Sales Amount] } ON 0,
    NON EMPTY
    { [Sales Territory].[Sales Territory Country].MEMBERS } ON 1
FROM
    [Adventure Works]
```

7. Execute the query. Notice that each year is replaced with a single month, the month with the best sales result in that year:

	December 2010	May 2011	January 2012	November 2013	January 2014
	Sales Amount	Sales Amount	Sales Amount	Sales Amount	Sales Amount
All Sales Territories	\$532,749.62	\$4,588,761.82	\$4,096,554.84	\$5,197,154.91	\$45,694.72
Australia	\$20,909.78	\$217,636.82	\$123,772.21	\$642,381.00	\$8,507.72
Canada	\$118,939.17	\$670,315.44	\$710,213.75	\$721,444.34	\$9,457.62
France	\$3,399.99	\$40,377.61	\$305,273.53	\$273,799.14	\$3,195.06
Germany	(null)	\$43,396.04	\$35,346.35	\$332,627.82	\$3,277.83
United Kingdom	\$699.10	\$26,966.90	\$229,176.93	\$626,859.86	\$3,713.64
United States	\$388,801.58	\$3,590,069.01	\$2,692,772.07	\$2,600,042.76	\$17,542.85

How it works...

The `Generate()` function can be thought of as a `for-each` loop. Its syntax is:

```
Generate( Set_Expression1 , Set_Expression2 [ , ALL ] )
```

This means that we can iterate through each member of the first set and assign each member from the second set. This second set can have zero, one, or many members and this can vary during the iteration. In our example, we're assigning a set with one member only, the best month in each year. That member is obtained using the `TopCount()` function where the first argument is months of the current year in iteration, the second argument is 1 (only one member to be returned), and the third argument is the `Sales Amount` measure the criterion for deciding which month is the best. Months are obtained the standard way, using the `Descendants()` function.

Notice that a different best month is displayed for each year, and that the use of the `Generate()` function is the only way to get this result. Simply cross-joining calendar years and the set of top one calendar months will display the top one calendar month for all time, repeated for each year. We can think of the first set in the `Generate()` function as the context of the looping.

There's more...

The `CurrentOrdinal` function is a special MDX function valid only in iterations. It returns the position of the current member (or tuple, to be precise) in the set in iteration (from 0 to N , where N is the total number of members in a set). In addition to that, there's also the `Current` function. The `Current` function returns the current tuple in a set being iterated. Again, it's only applicable during iterations.

Both of these functions can be used to detect the current tuple and to create various calculations with the current tuple and other tuples in that set. Reversing any initial set is one example of these manipulations. Comparing the value of the current tuple with the value of the previous tuple in the set (or any one before or after) to isolate certain tuples is another example.

You can reverse the set of months from the previous example as shown in the following screenshot:

	November 2013	January 2012	May 2011	December 2010
	Sales Amount	Sales Amount	Sales Amount	Sales Amount
All Sales Territories	\$5,197,154.91	\$4,096,554.84	\$4,588,761.82	\$532,749.62
Australia	\$642,381.00	\$123,772.21	\$217,636.82	\$20,909.78
Canada	\$721,444.34	\$710,213.75	\$670,315.44	\$118,939.17
France	\$273,799.14	\$305,273.53	\$40,377.61	\$3,399.99
Germany	\$332,627.82	\$35,346.35	\$43,396.04	(null)
United Kingdom	\$626,859.86	\$229,176.93	\$26,966.90	\$699.10
United States	\$2,600,042.76	\$2,692,772.07	\$3,590,069.01	\$388,801.58

The next query uses the CurrentOrdinal function and reverses the order of the months on the columns:

```
SET [Best month per year reversed] AS
    Generate( [Date].[Calendar].[Calendar Year].MEMBERS
        AS MySetAlias,
        TopCount(
            Descendants(
                MySetAlias.Item( MySetAlias.Count -
                    MySetAlias.CurrentOrdinal
                    - 1 ).Item(0),
                [Date].[Calendar].[Month],
                SELF ),
            1,
            [Measures].[Sales Amount] )
        )
```

A set alias (MySetAlias in this example) is defined for the initial set. That set alias is later used for navigation. The combination of Count and CurrentOrdinal gives us members from the end of the set to its beginning, progressively, while the Item() function serves as a pointer on members in that set.

Yes, the same operation could be done simply by sorting the months by their member key, in descending order. Nevertheless, the idea of this example was to show you the principle which can be applied on any set, especially those that can't be ordered easily.

The `CurrentOrdinal` function can also be used in the `Filter()` function. There, tuples can be compared with each other progressively to see which one has a value higher than both of its neighboring members, which would signal that the current member is a relative peak. Or the opposite, whatever is more interesting in a case. However, the `Filter()` function doesn't add new members; it only limits its initial set and for that reason, it is out of the scope of this recipe.

To summarize, both `Current` and `CurrentOrdinal` are powerful functions that allow us to perform the self-joining type of operations in MDX or make use of the existing relations between dimensions and measure groups. These functions are useful not only in the `Generate()` function, but also in other iterating functions as well, namely, the `Filter()` function.

Did you know?

In MDX, there's no concept of the `for` loop. Iterations cannot be based on numbers (as in other languages or on other systems). They must always be based on a set. If we need to loop exactly N times, there are two basic ways we can achieve this. One is with the existing cube structure; the other is by expanding a cube with a utility dimension. The former means that we can use the date dimension and take N members from its start. Or it could be some other dimension, if it has enough members to loop on. The other option is to use a utility dimension.

See also

- The *Iterating on a set using recursion* and *Iterating on a set to reduce it* recipes show other methods of iteration
- In *Chapter 8, When MDX is Not Enough, Using a dummy dimension to implement histograms over non-existing hierarchies* recipe shows how to iterate using utility dimension

Iterating on a set using recursion

Recursion is sometimes the best way to iterate a collection. Why? Because iterations using set functions (including the `Generate()` function) require that we loop through the whole set. But what if that set is big and we only need to find something specific in it? Wouldn't it be great to be able to stop the process when we've found what we wanted? Recursion enables just that to stop when we're done.

In this recipe, we are going to see how to calculate the average of an average using recursion.

Getting ready

To get started, start a new query in SSMS and check that you're working in the right database. Then write the following query:

```
SELECT  
    { [Measures].[Order Count] } ON 0,  
    NON EMPTY  
    { Descendants( [Date].[Fiscal Weeks].[All Periods],  
        1 , SELF_AND_BEFORE) } ON 1  
FROM  
    [Adventure Works]
```

It returns four fiscal years and their total on top for the `Order Count` measure. Now let's see how to calculate the average daily value on the week level and the average weekly level on the year level, which is based on the week level, not on the date level. In other words, each level will have the average value of members on the level immediately beneath.

How to do it...

Follow these steps to perform recursion over a set:

1. Define a new calculated measure and name it `Average of an average`.
2. Use the `iif()` function and specify its `True` parameter as the initial measure (`Order Count`).

3. The value should be returned for the leaf level, so the condition in `iif()` should test exactly that using the `IsLeaf()` function.
4. In the `false` parameter, we should provide the calculation we want to repeat recursively. In this case, it is the `Avg()` function used on the children of the current member.
5. The `[Measures]` expression inside the `Avg()` function should be the measure being defined.
6. Check whether the measure is defined as follows:

```
WITH
MEMBER [Measures].[Average of an average] AS
    iif( IsLeaf( [Date].[Fiscal Weeks].CurrentMember ),
        [Measures].[Order Count],
        Avg( [Date].[Fiscal Weeks].CurrentMember.Children,
            [Measures].[Average of an average] )
    )
, FORMAT_STRING = '#,#'
```

7. Don't forget to include that measure as the second measure on the columns.
8. Run the query. The results will look as follows. The first row, the one with the **All Periods** member, will have the average yearly value as the result, that is, $(49+72+236+479)/4=209$. In turn, every year will have the average weekly value. The weekly values are not visible in this screenshot, but we can divide the **Order Count** values by 53, which is the number of weeks per year. That should give us the values for the **Average of an average** measure for each year shown in the second column:

	Order Count	Average of an average
All Periods	30,584	209
FY 2010	1,327	49
FY 2011	3,817	72
FY 2012	12,505	236
FY 2013	12,935	479

How it works...

Recursions are the most difficult iteration concept to apply. Their logic is very condensed. However, once you conquer them, you'll appreciate their power and efficiency. Let us see how that solution worked.

To start the recursive process, we have to specify an expression that uses the same calculated measure we're defining, thereby providing a different input parameter than the one which was being used in the current pass of the recursive process. To stop the process, we must have a branch without the reference to that measure. On top of all that, we must perform some operation to collect values on the way. Complicated? Let us analyze our query.

It is helpful to examine the [Fiscal Weeks] hierarchy. In SSMS, starting a new MDX query, in the cube navigation pane, we can see the [Fiscal Weeks] hierarchy on the date dimension:

Notice that the **Fiscal Year** on the rows is not the leaf level of the [Fiscal Weeks] user hierarchy. Therefore, the expression inside the `iif()` statement evaluates as `False`. This leads us to the part where we have to calculate the average value for each child of the current member. With a small detail, the calculation should be performed using the same measure we're evaluating!

The evaluation for the current year member cannot be completed and is therefore delayed until the calculation for all its child members (weeks in this case) is performed. One by one, each week of the year in context is passed inside the definition of this measure and evaluated.

In the case of a leaf member, the `Order Count` measure would be evaluated and returned to the outer evaluation context. Otherwise, another turn of the child member's evaluation would occur. And so on until we finally hit the leaf-level members.

In this example, weeks are the leaf level of the hierarchy being used in the query. They would be evaluated using the `True` part of the condition. The `True` parameter is without reference to the measure we're calculating, which means the recursive path would be over. The value of the `Order Count` measure starting from the Week 1 of **FY 2010** would be collected and saved in a temporary buffer. The same process would be repeated for all weeks of that year. Only then would the average of them be calculated and returned as a value for **FY 2010**, after which the process would repeat for subsequent years on the rows.

Let us also mention that the value for the root member (`All years`) is calculated with the recursion depth of two, meaning each year it is first evaluated as an average of its weeks and then the average of its years is calculated and returned as the final result.

There's more...

You might be wondering, how does one recognize when to use recursion and when to use other types of iteration? Look for some of these pointers: relative positions, relative granulation for calculation, and stop logic. If there's a mention of going back or forth from the current member in a set, but there's no fixed span, then that might be a good lead to use recursion. If there's a relative stopping point, that's another sign. Finally, if there's no explicit requirement to loop through the whole set, but moreover a requirement to stop at some point in the process, that's a definite sign to try to apply recursion as a solution to the problem.

In case no such signs exist, it's perhaps better and easier to use the simple types of iterations we covered in previous recipes. The other case when you should consider straightforward iteration is when the recursion would span over more than half of the members on a hierarchy, which pushes the SSAS engine into the slow cell-by-cell mode.

Earlier versions of SSAS

SSAS 2008 and later have better support for recursion than previous versions of SSAS. Optimizations have been added to the code in the form of unlimited recursion depth. Versions prior to that may suffer from memory limitations in some extreme cases.

- The *Iterating on a set to create a new one* and *Iterating on a set to reduce it* recipes illustrate other ways of iteration

Performing complex sorts

Sorting is one of those often-requested operations. To sort a hierarchy by a measure is not a problem. Neither is to sort a hierarchy using its member properties. The MDX language has a designated function for that operation and a straightforward one too. Yes, we're talking about the `Order()` function.

Difficulties appear when we need to sort two or more hierarchies, one inside the other, or when we need to use two or more criteria. Not to mention the confusion when one of the members on the columns is supposed to be the criteria for sorting a related hierarchy on the rows. These are complex sort operations, operations we will cover in this recipe.

Let us build a case and see how it should be solved.

Getting ready

Start SSMS and connect to your SSAS 2016 instance. Click on the **New Query** button and check that the target database is Adventure Works DW 2016.

In this example, we are going to use the `Product` dimension, the `Sales Territory` dimension, and the `Date` dimension. Here is the query we will start from:

```
SELECT
    NON EMPTY
        { [Date].[Fiscal].[Fiscal Year].MEMBERS *
            [Measures].[Sales Amount] } ON 0,
    NON EMPTY
        { [Sales Territory].[Sales Territory Country]
            .[Sales Territory Country].MEMBERS *
            [Product].[Color].[Color].MEMBERS } ON 1
FROM
    [Adventure Works]
```

Once executed, the query returns 54 country-color combinations on the rows, four fiscal years on the columns, and the value of sales shown in the grid. No sort operation was applied. The countries and colors are returned in their default order alphabetically, as is visible in the following screenshot:

		FY 2010	FY 2011	FY 2012	FY 2013
		Sales Amount	Sales Amount	Sales Amount	Sales Amount
Australia	Black	\$173,064.59	\$633,697.98	\$1,378,618.60	\$856,695.35
Australia	Blue	(null)	(null)	\$658,150.93	\$671,130.98
Australia	Multi	(null)	(null)	\$11,457.38	\$10,724.39
Australia	NA	(null)	(null)	\$49,153.05	\$56,913.52
Australia	Red	\$985,873.21	\$1,206,627.99	\$386,354.04	\$102,469.55
Australia	Silver	\$129,199.62	\$307,298.91	\$661,887.33	\$423,867.64
Australia	Silver/Black	(null)	(null)	\$1,362.23	\$340.15
Australia	White	(null)	(null)	\$485.46	\$521.42
Australia	Yellow	(null)	\$31,013.56	\$804,708.58	\$1,113,719.49
Canada	Black	\$534,534.82	\$2,316,928.43	\$2,335,433.09	\$826,478.55
Canada	Blue	\$1,554.36	\$6,888.33	\$576,863.52	\$450,794.22
Canada	Multi	\$6,698.17	\$58,457.12	\$53,139.51	\$21,186.05
Canada	NA	(null)	\$37,526.91	\$93,508.92	\$66,364.22
Canada	Red	\$689,223.56	\$2,141,280.10	\$688,856.88	\$54,052.45
Canada	Silver	\$308,760.13	\$924,117.65	\$1,066,115.81	\$559,142.13
Canada	Silver/Black	(null)	(null)	\$19,288.62	\$8,953.38
Canada	White	\$479.05	\$531.60	\$2,161.39	\$1,374.92
Canada	Yellow	(null)	\$338,300.30	\$1,328,120.66	\$838,655.63
France	Black	\$23,745.43	\$564,770.67	\$1,142,757.83	\$589,435.01
France	Blue	(null)	\$1,231.38	\$547,648.30	\$431,220.30
France	Multi	(null)	\$13,305.09	\$20,128.13	\$11,998.05
France	NA	(null)	\$7,734.90	\$45,711.81	\$36,103.16
France	Red	\$146,626.29	\$554,377.77	\$323,332.61	\$26,677.49

To sort the rows by a particular value, you could simply wrap the `Order()` function around them. For example, to sort the previous result by the **Sales Amount** in **FY 2013**, you would have to change the set on the rows like this:

```
Order(
    [Sales Territory].[Sales Territory Country]
        .[Sales Territory Country].MEMBERS *
    [Product].[Color].[Color].MEMBERS,
    ( [Date].[Fiscal].[Fiscal Year].&[2013],
        [Measures].[Sales Amount] ),
    BDESC )
```

The following screenshot shows the result of the modified query:

		FY 2010	FY 2011	FY 2012	FY 2013
		Sales Amount	Sales Amount	Sales Amount	Sales Amount
United States	Yellow	(null)	\$1,089,546.79	\$5,024,226.44	\$3,543,913.87
United States	Black	\$2,424,746.18	\$8,760,223.31	\$8,592,041.59	\$3,407,038.93
United States	Silver	\$2,013,058.92	\$3,947,429.83	\$4,064,892.02	\$2,264,783.85
United States	Blue	\$4,893.62	\$19,022.98	\$2,399,657.32	\$1,855,262.52
Australia	Yellow	(null)	\$31,013.56	\$804,708.58	\$1,113,719.49

Canada	Yellow	(null)	\$338,300.30	\$1,328,120.66	\$838,655.63
Canada	Black	\$534,534.82	\$2,316,928.43	\$2,335,433.09	\$826,478.55
France	Yellow	(null)	\$105,888.41	\$793,170.77	\$795,255.57
United Kingdom	Yellow	(null)	\$79,050.11	\$782,105.48	\$724,709.91
United Kingdom	Black	\$24,565.03	\$630,172.51	\$1,246,335.58	\$697,303.17
Australia	Blue	(null)	(null)	\$658,150.93	\$671,130.98
France	Black	\$23,745.43	\$564,770.67	\$1,142,757.83	\$589,435.01
Germany	Yellow	(null)	\$16,007.00	\$693,290.96	\$567,821.68
Canada	Silver	\$308,760.13	\$924,117.65	\$1,066,115.81	\$559,142.13
Germany	Blue	(null)	(null)	\$571,904.12	\$468,267.52
United Kingdom	Blue	(null)	\$1,322.22	\$469,187.65	\$467,850.70
Canada	Blue	\$1,554.36	\$6,888.33	\$576,863.52	\$450,794.22
France	Blue	(null)	\$1,231.38	\$547,648.30	\$431,220.30
Australia	Silver	\$129,199.62	\$307,298.91	\$661,887.33	\$423,867.64
Germany	Black	\$29,217.72	\$136,627.85	\$493,994.17	\$417,697.66
United Kingdom	Silver	\$37,399.89	\$256,707.02	\$627,542.86	\$412,726.11

This time the rows are returned in descending order in respect to the last column, highlighted in the screenshot. But, notice one thing—countries and colors are mixed.

Breaking their sequence like that will rarely be asked for. More often, the request will be to sort one hierarchy inside the other, the rightmost inside those on its left. In other words, we will try to sort colors inside each country. Now let us see how this can be done.

How to do it...

Follow these steps to sort hierarchies on the rows, one inside the other:

1. Modify the set on the rows like this:

```
{ Generate(
    [Sales Territory].[Sales Territory Country]
        .[Sales Territory Country].MEMBERS,
    [Sales Territory].[Sales Territory Country]
        .CurrentMember *
    Order( [Product].[Color].[Color].MEMBERS,
        ( [Date].[Fiscal].[Fiscal Year].&[2009],
            [Measures].[Sales Amount] ),
        BDESC
    )
) }
```

2. Execute the query. The result should match the following screenshot:

		FY 2010	FY 2011	FY 2012	FY 2013
		Sales Amount	Sales Amount	Sales Amount	Sales Amount
Australia	Yellow	(null)	\$31,013.56	\$804,708.58	\$1,113,719.49
Australia	Black	\$173,064.59	\$633,697.98	\$1,378,618.60	\$856,695.35
Australia	Blue	(null)	(null)	\$658,150.93	\$671,130.98
Australia	Silver	\$129,199.62	\$307,298.91	\$661,887.33	\$423,867.64
Australia	Red	\$985,873.21	\$1,206,627.99	\$386,354.04	\$102,469.55
Australia	NA	(null)	(null)	\$49,153.05	\$56,913.52
Australia	Multi	(null)	(null)	\$11,457.38	\$10,724.39
Australia	White	(null)	(null)	\$485.46	\$521.42
Australia	Silver/Black	(null)	(null)	\$1,362.23	\$340.15
Canada	Yellow	(null)	\$338,300.30	\$1,328,120.66	\$838,655.63
Canada	Black	\$534,534.82	\$2,316,928.43	\$2,335,433.09	\$826,478.55
Canada	Silver	\$308,760.13	\$924,117.65	\$1,066,115.81	\$559,142.13
Canada	Blue	\$1,554.36	\$6,888.33	\$576,863.52	\$450,794.22
Canada	NA	(null)	\$37,526.91	\$93,508.92	\$66,364.22
Canada	Red	\$689,223.56	\$2,141,280.10	\$688,856.88	\$54,052.45
Canada	Multi	\$6,698.17	\$58,457.12	\$53,139.51	\$21,186.05
Canada	Silver/Black	(null)	(null)	\$19,288.62	\$8,953.38
Canada	White	\$479.05	\$531.60	\$2,161.39	\$1,374.92
France	Yellow	(null)	\$105,888.41	\$793,170.77	\$795,255.57
France	Black	\$23,745.43	\$564,770.67	\$1,142,757.83	\$589,435.01
France	Blue	(null)	\$1,231.38	\$547,648.30	\$431,220.30
France	Silver	\$6,799.98	\$164,854.74	\$523,248.80	\$362,594.81

Notice that colors are ordered this time in descending order inside each country. Notice also that their sequence changes from country to country (**Blue** is the third in **Australia**, **Silver** is the third in **Canada**).

How it works...

Do you remember a recipe earlier in this chapter about creating a new set from the old one using iteration? Yes, *Iterating on a set to create a new one* is its name. The function used in that recipe is the same one used in this recipe—the `Generate()` function, which takes a set (single or multi-dimensional one) and creates a new set the way we specify in the second argument of that function.

What is important to note is that we have used only the first hierarchy on the rows, not both. The `Generate()` function has no problem in creating a multi-dimensional set from the single-dimensional one. In fact, that's exactly what was needed in this case. We had to preserve the outer hierarchy's order. We've used it as the first argument of the `Generate()` function and cross-joined each of its members with the set of colors ordered by the required criteria. It may not be obvious, but the criteria also implicitly included the current country. That's because `Generate()` is a loop function that sets its own context instead of modifying the existing one. Consequently, the colors came ordered differently in each country.

There's more...

Sorting the rightmost hierarchy inside the one on the left is fine, but what if we also need to sort the outer one? What if the requirement says, *return the countries in descending order by the same criteria and then only return colors sorted inside each country?* Can we deliver that as well? Yes, and here's how.

Modify the set on the rows this way:

```
{ Generate(
    Order( [Sales Territory].[Sales Territory Country]
          .[Sales Territory Country].MEMBERS,
        ( [Date].[Fiscal].[Fiscal Year].&[2009],
          [Measures].[Sales Amount] ),
        BDESC
      ),
    [Sales Territory].[Sales Territory Country].CurrentMember *
    Order( [Product].[Color].[Color].MEMBERS,
      ( [Date].[Fiscal].[Fiscal Year].&[2009],
        [Measures].[Sales Amount] ),
        BDESC
```

```
)  
) }
```

If you take a close look, you will notice not much has changed. All that we have done extra this time is that we have ordered the initial set in the `Generate()` function so that it preserves the order when we *cross join* its members with the other set.

The result of this modification is shown in the following screenshot:

		FY 2010	FY 2011	FY 2012	FY 2013
		Sales Amount	Sales Amount	Sales Amount	Sales Amount
United States	Yellow	(null)	\$1,089,546.79	\$5,024,226.44	\$3,543,913.87
United States	Black	\$2,424,746.18	\$8,760,223.31	\$8,592,041.59	\$3,407,038.93
United States	Silver	\$2,013,058.92	\$3,947,429.83	\$4,064,892.02	\$2,264,783.85
United States	Blue	\$4,893.62	\$19,022.98	\$2,399,657.32	\$1,855,262.52

United States	White	\$2,709.75	\$2,853.00	\$9,388.96	\$6,191.53
Australia	Yellow	(null)	\$31,013.56	\$804,708.58	\$1,113,719.49
Australia	Black	\$173,064.59	\$633,697.98	\$1,378,618.60	\$856,695.35
Australia	Blue	(null)	(null)	\$658,150.93	\$671,130.98
Australia	Silver	\$129,199.62	\$307,298.91	\$661,887.33	\$423,867.64
Australia	Red	\$985,873.21	\$1,206,627.99	\$386,354.04	\$102,469.55
Australia	NA	(null)	(null)	\$49,153.05	\$56,913.52
Australia	Multi	(null)	(null)	\$11,457.38	\$10,724.39
Australia	White	(null)	(null)	\$485.46	\$521.42
Australia	Silver/Black	(null)	(null)	\$1,362.23	\$340.15
Canada	Yellow	(null)	\$338,300.30	\$1,328,120.66	\$838,655.63
Canada	Black	\$534,534.82	\$2,316,928.43	\$2,335,433.09	\$826,478.55
Canada	Silver	\$308,760.13	\$924,117.65	\$1,066,115.81	\$559,142.13
Canada	Blue	\$1,554.36	\$6,888.33	\$576,863.52	\$450,794.22

Look at the query one more time and you will notice there are two criteria in it, both the same. It does not take a lot of imagination to conclude that they do not have to be the same. Yes, you can have different criteria; simply modify any of them and test. Having learned this much about sorting, you can confidently perform complex sorts.

Things to be extra careful about

Write this query, but do not execute it yet!

```
SELECT
    NON EMPTY
    { [Product].[Product Line].[Product Line].MEMBERS *
      [Measures].[Sales Amount] } ON 0,
    NON EMPTY
    { Generate(
        [Sales Territory].[Sales Territory Country]
        .[Sales Territory Country].MEMBERS,
        [Sales Territory].[Sales Territory Country]
        .CurrentMember *
        Order( [Product].[Model Name].[Model Name].MEMBERS,
              ( [Product].[Product Line].&[M],
                -- [Product].[Model Name].CurrentMember,
                [Measures].[Sales Amount] ),
              BDESC )
        ) } ON 1
FROM
    [Adventure Works]
```

If you analyze the code, you will notice that the same idea is used to sort the results based on one of the columns. This time, however, the hierarchies on the rows and columns are related. The Model Name and the Product Line attribute hierarchies can be found in the Product Model Lines user hierarchy. In short, models are grouped by the product lines.

Now, run the query and observe the result:

		Accessory	Components	Mountain	Road	Touring
		Sales Amount				
Australia	All-Purpose Bike Stand	(null)	(null)	\$10,335.00	(null)	(null)
Australia	Bike Wash	\$2,286.42	(null)	(null)	(null)	(null)
Australia	Chain	(null)	\$850.08	(null)	(null)	(null)
Australia	Classic Vest	\$21,065.62	(null)	(null)	(null)	(null)
Australia	Cycling Cap	\$4,828.75	(null)	(null)	(null)	(null)
Australia	Fender Set - Mountain	(null)	(null)	\$7,143.50	(null)	(null)
Australia	Front Brakes	(null)	\$3,770.10	(null)	(null)	(null)
Australia	Front Derailleur	(null)	\$5,214.93	(null)	(null)	(null)
Australia	Half-Finger Gloves	\$9,771.75	(null)	(null)	(null)	(null)
Australia	Hitch Rack - 4-Bike	\$18,406.70	(null)	(null)	(null)	(null)
Australia	HL Bottom Bracket	(null)	\$3,426.02	(null)	(null)	(null)
Australia	HL Crankset	(null)	\$13,364.67	(null)	(null)	(null)
Australia	HL Mountain Frame	(null)	(null)	\$21,997.62	(null)	(null)
Australia	HL Mountain Handlebars	(null)	(null)	\$72.16	(null)	(null)
Australia	HL Mountain Pedal	(null)	(null)	\$777.50	(null)	(null)
Australia	HL Mountain Seat/Saddle 2	(null)	(null)	\$189.50	(null)	(null)
Australia	HL Mountain Tire	(null)	(null)	\$8,400.00	(null)	(null)
Australia	HL Road Tire	(null)	(null)	(null)	\$5,444.20	(null)
Australia	HL Touring Frame	(null)	(null)	(null)	(null)	\$104,427.52

Oops, it does not look good; there is no trace of any sort in it. Now uncomment the commented line and run it again. All good, the result is ordered by the middle column, the **Mountain** model:

		Accessory	Components	Mountain	Road	Touring
		Sales Amount	Sales Amount	Sales Amount	Sales Amount	Sales Amount
Australia	Mountain-200	(null)	(null)	\$2,171,361.25	(null)	(null)
Australia	Mountain-100	(null)	(null)	\$670,498.02	(null)	(null)

What's going on?

Remember what we said about current members being implicit in the sort criteria? The same applies here. Both the country and the model are in the tuple that determines the sort.

In the examples we started this recipe with, all the hierarchies were unrelated and no problem was noticed. This time, they were related and behaved differently because related hierarchies interfere with each other. In other words, the `Mountain` member of the `Product Line` attribute hierarchy pushed the current member of the `Model Name` attribute hierarchy to its root member. The relation between them is `1:N`; the models are below the product lines. Consequently, all models evaluated the same in that tuple, as the value of the `Mountain` product line for a particular country. Sorting members by a constant value leaves them in their existing order. That is the result we got in the first screenshot.

On the other hand, when we are explicit about the current member of the `Model Name` attribute hierarchy in the tuple for the sort criteria, we get the correct result.

The difference is that this time we have specified the intersection of related hierarchies. In other words, we were referring to the individual cells found in the intersection of the models and the product lines. Those cells are exactly what we needed, each different from another and hence returning results sorted the way we wanted.

Remember this and do not forget to force the coordinate in case there are related hierarchies, when the hierarchy on the columns is above the hierarchy on the rows in terms of attribute paths.

A costly operation

Sorting is a costly operation. If you have large dimensions, always look for an alternative solution. For example, if you do not need the entire set, use set-limiting functions such as `NonEmpty()`, `TopCount()`, and others.

Dissecting and debugging MDX queries

When writing a query involving complex calculations, you might have a hard time trying to debug it, if there is a problem inside the calculation. But there is a way. By breaking complex sets and calculations into smaller pieces and/or by converting those sets and members into strings, we can visually represent the intermediate results and thereby isolate the problematic part of the query.

True, there is no real debugger in the sense that you can pause the calculation process of the query and evaluate the variables. What you can do is to simulate that by concatenating intermediate results into strings for visual verification.

Getting ready

For this recipe, we will use the final query in the previous recipe, *Iterating on a set using recursion*. We have chosen this as our example because it is a relatively complex calculation and we want to check whether we are doing the right thing.

How to do it...

Follow these steps to create a calculated measure that shows the evaluation of another calculation:

1. Start SSMS and execute the following query:

```
WITH
MEMBER [Measures].[Average of an average] AS
    iif( IsLeaf( [Date].[Fiscal Weeks].CurrentMember ),
        [Measures].[Order Count],
        Avg( [Date].[Fiscal Weeks].CurrentMember.Children,
            [Measures].[Average of an average] )
    )
    , FORMAT_STRING = '#,#'
SELECT
    { [Measures].[Order Count],
        [Measures].[Average of an average] } ON 0,
    NON EMPTY
    { Descendants( [Date].[Fiscal Weeks].[All Periods],
                    1 , SELF_AND_BEFORE) } ON 1
FROM
    [Adventure Works]
```

2. Create a new calculated measure and name it **Proof**.
3. Copy the definition of the [Average of an average] measure and paste it as the definition of the new calculated measure **Proof**.
4. Leave the **True** part as it is.
5. Modify the **False** part as shown in the next step.
6. Finally, wrap the whole expression with one **iif()** statement that checks whether the original measure is empty. The definition of that measure should look like this:

```
MEMBER [Measures].[Proof] AS
    iif( IsEmpty( [Measures].[Order Count] ),
        null,
        iif( IsLeaf( [Date].[Fiscal Weeks].CurrentMember ),
            [Measures].[Order Count],
            '(' +
            Generate( [Date].[Fiscal Weeks]
                .CurrentMember.Children,
                iif( IsEmpty( [Measures]
                    .[Average of an average] ),
                    '(null)',
                    CStr(
                        Round( [Measures]
                            .[Average of an average],
                            0 ) )
                ),
                ' + ' ) +
                ' ) / ' +
                CStr( NonEmpty( [Date].[Fiscal Weeks]
                    .CurrentMember.Children,
                    [Measures].[Order Count]
                ).Count )
            )
        )
    )
```

7. Add that measure onto the columns and execute the query. The result will look like this:

	Order Count	Proof	Average of an average
All Periods	30,584	((null) + (null) + (null) + (null) + (null) + 49 + 72 + 236 + 479 + (null)) / 4	209
FY 2010	1,327	(36 + (null) + (n...)	49
FY 2011	3,817	(49 + 39 + 46 + 45 + 42 + 128 + 45 + 34 + 45 + 111 + 42 + 49 + 44 + 76 + 39 + 54 + 45...)	72
FY 2012	12,505	(193 + 62 + 54 + 51 + 200 + 65 + 72 + 70 + 166 + 66 + 64 + 46 + 145 + 66 + 68 + 60 + ...)	236
FY 2013	12,935	(344 + 431 + 443 + 415 + 604 + 445 + 457 + 444 + 606 + 446 + 423 + 456 + 430 + 579...)	479

How it works...

The general idea of debugging MDX queries is to display some intermediate results, such as the current member names, their properties, positions in a set, their descendants, and ancestors, to help us with visual verification. At other times, we will convert the complete sets that we are operating with into a string, just to see the members inside, and their order. For numeric values, if they are formed using several sub-calculations like in this example, we try to compose that evaluation as a string too. In short, we're displaying textual values of items we are interested in.

In our example, the main part that we want to verify is the `False` parameter of the inner `iif()` function, that is, when the fiscal week hierarchy is not at the leaf level. Therefore, that is the place where we are building a concatenated string to show how the average of an average is calculated.

The preceding screenshot can help us to understand how the measure `Proof` is concatenated. It is a string representation of all individual values used to calculate each row of `Average of an average`. It is represented as a sum of N values, where N is the number of children of the current member, divided by their count. Additionally, null values are preserved and displayed as well in the string, but the count omits them.

Now, the calculation for the measure `Proof` itself. First, there is an open bracket in the form of a string. Then the `Generate()` function is applied, only this time it is the second version of that function, the one that returns not a set but a string. More information about it can be found at <http://tinyurl.com/MDXGenerate>.

The `Generate()` function has two different usages with two different syntaxes. We have seen its first usage in a previous recipe, *Iterating on a set to create a new one*, where the `Generate()` function is used to evaluate a complex set expression, such as `TopCount()`, over a set of members. In this recipe, we have used its second syntax, in which a string expression is evaluated over a set of members, and the strings are eventually concatenated and returned, separated by a delimiter of either a plus sign or parentheses. The syntax is shown as follows:

```
Generate( Set_Expression1, String_Expression, Delimiter)
```

Partial strings generated during iteration need to be concatenated. For that reason, the third argument of the `Generate()` function was used with the value `+`.

The `Generate()` function, as explained in the *Iterating on a set to create a new one* recipe, is a type of loop. In this case, it takes each child of a current member of the **Fiscal Weeks** user hierarchy and tests whether it is empty or not. If it is, a constant string is used (`((null))`); if not, the value of the measure is rounded to zero decimals.

Which measure? That same measure we are calculating the result for. Hence, it is again a call for iteration, this time using each child, one by one, because they are in the context at the time of the call.

In the new pass, those members will be leaf members. They will collect the value of the measure `Order Count` and get out of that pass.

Once all the children are evaluated, the individual values will be concatenated using a `+` sign with a space on each side for better readability.

But the process is not over; only the recursion is.

Next, we must close the bracket which we opened in the beginning of the process, and we have to calculate the denominator. Notice the measure inside the denominator is not calling for recursion. To get the count of members, we used the `NonEmpty()` function over the original measure. That returns the members which have values.

Finally, we have not mentioned this specifically so far, but the outer `iif()` statement checks whether we are on a member that has no result. If so, we can skip that member. Remember, we had to do that because the inner part of the `Proof` measure is a string which is never null.

There's more...

In the process of dissecting, evaluating, and debugging calculations and queries, various MDX functions can be used. Some of them are mentioned here. However, it is advised that you look for additional information on MSDN and other sources:

- String functions, namely `MemberToStr()` and `SetToStr()`, for converting members and sets into strings
- Set functions, namely the `Generate()` function and especially its string variant, which is a very powerful method for iterating on a set, and for collecting partial calculations in the form of strings

- Metadata functions (also known as hierarchy and level functions), for collecting information about members and their hierarchies
- Logical functions, for testing on the leaf level and emptiness
- VBA functions, for handling errors (`IsError()`) and string manipulations

Don't forget to use the `AddCalculatedMembers()` function if you need to include calculated members.

Useful string functions

A list of VBA functions that can be used in MDX can be found at:

<http://tinyurl.com/MDXVBAFunction>

A list of MDX functions grouped by types can be found at:

<http://tinyurl.com/MDXfunctions>

- The *Optimizing MDX queries using the NonEmpty() function* recipe in Chapter 1, *Elementary MDX Techniques*, shows how to keep only relevant members for debugging purposes and prevent all members of a hierarchy from being returned as the result

Implementing the logical AND on members from the same hierarchy

This recipe shows how to implement the AND logic using members from the same hierarchy.

In the Adventure Works DW 2016 database, there are two members, [New Product] and [Excess Inventory], in the [Promotion Type] hierarchy:

```
[Promotion].[Promotion Type].&[New Product]  
[Promotion].[Promotion Type].&[Excess Inventory]
```

These two promotion types have reseller orders, but the only two months in which they both have reseller orders are January and December.

The idea is to have a single query that displays the reseller orders, where both promotion types occur in the same month. In other words, we want to show the reseller orders for January and December.

Our goal is to somehow combine these two members from the same hierarchy so that we perform the logical AND along the [Month of Year] hierarchy on the Date dimension.

Getting ready

Start a new query in SSMS and make sure that you're working on the Adventure Works DW 2016 database.

Our first query will slice the cube by the [New Product] promotion type. The query is as follows. Let us execute it:

```
SELECT
    { [Measures].[Reseller Order Quantity],
      [Measures].[Reseller Order Count] } ON 0,
  NON EMPTY
    { [Date].[Month of Year].MEMBERS } ON 1
FROM
    [Adventure Works]
WHERE
    ( [Promotion].[Promotion Type].&[New Product] )
```

The query displays three months from the [Month of Year] hierarchy with the New Product promotion type, January, February, and December, with the top level [All periods]. The result should be the same as shown in the following screenshot.

For [New Product]:

	Reseller Order Quantity	Reseller Order Count
All Periods	2,323	116
January	811	39
February	999	53
December	513	24

Let us replace the new product with the Excess Inventory promotion type; we will get one month less with only January and December. See the query and the result as shown:

```
SELECT
    { [Measures].[Reseller Order Quantity],
      [Measures].[Reseller Order Count] } ON 0,
  NON EMPTY
    { [Date].[Month of Year].MEMBERS } ON 1
FROM
    [Adventure Works]
WHERE
    ( [Promotion].[Promotion Type].&[Excess Inventory] )
```

For [Excess Inventory]:

	Reseller Order Quantity	Reseller Order Count
All Periods	304	61
January	169	37
December	135	24

The idea is to have a single query which displays the result where both of these promotion types occur in the same month. In other words, we want to show the values for January and December.

We have several ways of doing it, but this recipe will focus on the slicer-subselect solution. Other solutions will be mentioned in further sections of this recipe.

Our result should be as follows:

	Reseller Order Quantity	Reseller Order Count
All Promotions	1,628	124
Excess Inventory	304	61
New Product	1,324	63

How to do it...

Our goal is to somehow combine these two members from the same hierarchy so that we perform the logical AND along the [Month of Year] hierarchy on the Date dimension:

```
WHERE
  ( [Promotion].[Promotion Type].&[New Product] )
WHERE
  ( [Promotion].[Promotion Type].&[Excess Inventory] )
```

To perform an AND logic on different members from the same hierarchy, we must nest our conditions:

1. Here is our innermost condition, where we are using the `Exists()` function to get the month of year that has Reseller Sales for Excess Inventory. Notice that Reseller Sales is our measure group of interest. The `Exists()` function takes two set expressions and one measure group, and returns a set of tuples from the first set that exist with one or more tuples in the second set. The returned set of tuples must be associated with the measure group. This innermost condition will return January, February, and December in our example because they are the only three months that have reseller sales for New Product.
2. Also notice that we are using the Month of Year level (not hierarchy!) as the first parameter. The level has a three-part syntax; hierarchy has a two-part syntax. Do not omit the third part, otherwise it won't work:

```
Exists(
  { [Date].[Month of Year].[Month of Year].MEMBERS },
  { [Promotion].[Promotion Type].&[New Product] },
  "Reseller Sales"
)
```

3. We are going to use this inner condition as a nested condition, and wrap it with another `Exists()` function. The outer `Exists()` function also takes two sets and one measure group. With the first set being January, February, and December, and the second set being the excess inventory, only January and December are returned. February will be filtered out because it no longer has reseller sales for [Excess Inventory]:

```
WHERE
  (
    Exists(
      Exists(
        { [Date].[Month of Year].[Month of Year].MEMBERS },
        { [Promotion].[Promotion Type].&[New Product] },
```

```
        "Reseller Sales"
        ),
{ [Promotion].[Promotion Type].&[Excess Inventory] },
"Reseller Sales"
)
)
```

4. We have worked out of the slicer so far. We also need a subselect with those two members [New Product] and [Excess Inventory] inside (see the subselect that follows):

```
FROM
(
    SELECT
        { [Promotion].[Promotion Type].&[New Product],
          [Promotion].[Promotion Type].&[Excess Inventory] } ON 0
    FROM
        [Adventure Works]
)
```

5. Here is the final query. Let's run it:

```
SELECT
    { [Measures].[Reseller Order Quantity],
      [Measures].[Reseller Order Count] } ON 0,
NON EMPTY
    { [Promotion].[Promotion Type].MEMBERS } ON 1
FROM
(
    (
        SELECT
            { [Promotion].[Promotion Type].&[New Product],
              [Promotion].[Promotion Type].&[Excess Inventory] }
            ON 0
        FROM
            [Adventure Works]
    )
WHERE
(
    Exists(
        Exists(
            { [Date].[Month of Year].[Month of Year].MEMBERS },
            { [Promotion].[Promotion Type].&[New Product] },
            "Reseller Sales"
        ),
        { [Promotion].[Promotion Type].&[Excess Inventory] },
        "Reseller Sales"
    )
)
```

6. The result of the query shows the aggregate for January and December, the only two months where both promotion types occur:

	Reseller Order Quantity	Reseller Order Count
All Promotions	1,628	124
Excess Inventory	304	61
New Product	1,324	63

7. Compare these results with the tables at the beginning of this recipe (showing a combination of promotion types and months) and you will notice that the aggregates match the sum of individual values.

How it works...

In the introduction, we stated that our goal is to have a single query that displays the reseller orders where both of these promotion types occur in the same month. Since there is no MDX expression that would work and return the logic AND result using two members from the same hierarchy, the [Month of Year] hierarchy has become our base for performing the AND logic.

To perform the AND logic on the same hierarchy, we must cascade the conditions using an inner set and an outer set. The inner set is repeated here:

```
Exists( { [Date].[Month of Year].[Month of Year].MEMBERS },
        { [Promotion].[Promotion Type].&[New Product] },
        "Reseller Sales"
    )
```

This inner set returns all the months that have the New Product promotion type (three months as seen on the initial screenshot).

The outer set restricts the inner set even more by filtering out all months that don't have the other promotion type as well. That leaves only two months, **January** and **December**.

We have chosen the [Month of Year] hierarchy as our base to perform the AND logic. In practice, we will need to decide which hierarchy and which level we want to use as the new base or granularity and adhere to some common sense rules.

Firstly, the relationship between the new hierarchy's level members and the members for slicing should be many-to-many. This is always so in case of different dimensions (Promotion and Date), a case covered in this example. In case of the same dimension, the solution will work only for a single member that is related to both members in the AND operation. Whether that will be something other than the All member depends on the hierarchy and members selected for the AND operation. For example, two promotion types used in this example share only one ancestor—the All member, which can be verified in the Promotion user hierarchy of that dimension.

Secondly, the whole idea should be valid. In practice, we can run multiple promotions in the same month. Therefore, on the granularity of the month, two different promotions can have intersections on the same order, and our idea is valid.

Which hierarchy to use? That usually becomes obvious once we ask ourselves the question behind the report. For example, the last query, as seen in the previous screenshot, returned the two promotion types we started with in this recipe, promotion types that come together on a monthly basis. Two things are important here: **together** and **basis**. The term together represents the AND logic. The term monthly basis is in fact the new granularity for the report (that which goes in the slicer).

That explains the slicer part of the solution. What about the subselect part? Why is it there?

The subselect part serves the purpose of adjusting the results. Without it, we would get the wrong total. Let me explain this in more detail.

If you remove the subselect part of the query and execute it again, it will return the result displayed in the following screenshot:

	Reseller Order Quantity	Reseller Order Count
All Promotions	46,429	603
Excess Inventory	304	61
New Product	1,324	63
No Discount	35,096	596
Seasonal Discount	1,172	66
Volume Discount	8,533	158

The cell numbers for **New Product** and **Excess Inventory** on this screenshot match the aggregated values displayed in the previous screenshot.

However, the query returned all the promotion types because nothing limited them in the query. The slicer effectively limits the months only, not the promotion types.

There are two things we can do to correct this, that is, to display the result for those two hierarchies only. One is to put them in the slicer so that they cross-join with the existing slicer. The other is to put them in a subselect. I prefer the second option because this way we can still have them on a query axis. Otherwise, we will have a conflict with the slicer (a hierarchy cannot appear in the slicer and on an axis, but it can appear in the subselect and also on an axis). That's why we have chosen the subselect.

The subselect, as seen before, limits the promotion types that appear on an axis and adjusts their total so that it becomes the visual total for those two members. This is exactly what we need, the value for individual promotion types and their correct total.

To conclude, to implement the `AND` logic, we have done two things. First, we have established a new granularity in the slicer. Second, we used the subselect to adjust the total.

There's more...

This is not the only way to implement the `AND` logic. We can do it on an axis as well. In that case, all we should do is put a construct from the slicer on the rows and leave the subselect as it is.

Where to put what?

Based on a request, the `AND` logic can be implemented on the rows or in the slicer. If there is a request to hide the hierarchy for which we are applying the `AND` logic, we should put the corresponding MDX expression in the slicer. On the other hand, if there is an explicit request to show members on the rows, we must put the construct on the rows. There, we can *crossjoin* it with additional hierarchies if required.

A very complex scenario

In the event of a more complex scenario where three different hierarchies need to be combined, we can apply the same solution, which, in a general case, should have N cascades in the slicer and N members in the subselect. The N is the number of members from the same hierarchy.

In the event that we need to combine many members using the AND logic, some of them originating from different hierarchies and some from the same, the solution becomes very complex.

You are advised to watch out for the order in the cascades and dimensionality of the potential tuples.

3

Working with Time

In this chapter, we will cover the following recipes:

- Calculating the Year-To-Date (YTD) value
- Calculating the Year-over-Year (YoY) growth (parallel periods)
- Calculating moving averages
- Finding the last date with data
- Getting values on the last date with data
- Calculating today's date using the STRING functions
- Calculating today's date using the MemberValue function
- Calculating today's date using an attribute hierarchy
- Calculating the difference between two dates
- Calculating the difference between two times
- Calculating parallel periods for multiple dates in a set
- Calculating parallel periods for multiple dates in a slicer

Introduction

Time-handling features are an important part of every **Business Intelligence (BI)** system. Programming languages, database systems, they all incorporate various time-related functions and Microsoft SQL Server Analysis Services (SSAS) is no exception there. In fact, that's one of its main strengths.

The MDX language has various time-related functions designed to work with a special type of dimension called `Time` and its typed attributes. While it's true that some of those functions work with any type of dimension, their usefulness is most obvious when applied to time-type dimensions. An additional prerequisite is the existence of multi-level hierarchies, also known as user hierarchies, in which types of levels must be set correctly or some of the time-related functions will either give false results or will not work at all.

Because of the reasons described earlier, and the fact that almost every cube will have one or more time dimensions, we've decided to dedicate a whole chapter to this topic, that is, for time calculations. In this chapter, we're dealing with typical operations, such as year-to-date calculations, running totals, and jumping from one period to another. We go into detail with each operation, explaining known and less known variants and pitfalls.

We will discuss why some time calculations can create unnecessary data for the periods that should not have data at all, and why we should prevent it from happening. We will then show you how to prevent time calculations from having values after a certain point in time.

In most BI projects, there are always reporting requirements to show measures for today, yesterday, month-to-date, quarter-to-date, year-to-date, and so on. We have three recipes to explore various ways to calculate today's date, and how to turn it into a set and use MDX's powerful set operations to calculate other related periods.

Calculating date and time spans is also a common reporting requirement.

The chapter ends with two recipes explaining how to calculate the parallel period for a range of dates.

Calculating the year-to-date (YTD) value

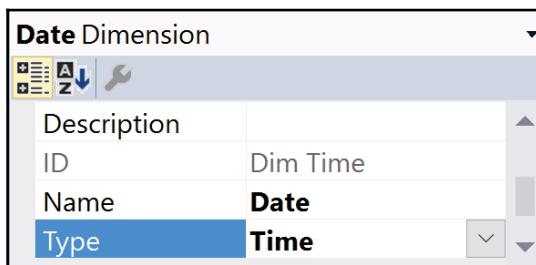

In this recipe, we will look at how to calculate the YTD value of a measure, that is, the accumulated value of all dates in a year up to the current member on the date dimension. An MDX function `YTD()` can be used to calculate the Year-To-Date value, but not without its constraints.

In this recipe, we will discuss the constraints when using the `YTD()` function and also the alternative solutions.

Getting ready

Start SSMS and connect to your SQL Server Analysis Services (SSAS) 2016 instance. Click on the New Query button and check that the target database is Adventure Works DW 2016.

In order for this type of calculation to work, we need a dimension marked as **Time** in the **Type** property, in the Dimension structure tab of SQL Server Data Tools (SSDT). That should not be a problem because almost every database contains at least one such dimension and Adventure Works is no exception here. In this example, we're going to use the **Date Dimension**. We can verify in SSDT that the **Date** dimension's **Type** property is set to **Time**. See the following screenshot from SSDT:

Here's the query we'll start from:

```
SELECT
    { [Measures].[Reseller Sales Amount] } ON 0,
    { [Date].[Calendar Weeks].[Calendar Week].MEMBERS } ON 1
FROM
    [Adventure Works]
```

Once executed, the preceding query returns reseller sales values for every week in the database.

How to do it...

We are going to use the `YTD()` function, which takes only one member expression, and returns all dates in the year up to the specified member. Then we will use the aggregation function `Sum()` to sum up the Reseller Sales Amount.

Follow these steps to create a calculated measure with YTD calculation:

1. Add the WITH block of the query.
2. Create a new calculated measure within the WITH block and name it Reseller Sales YTD.
3. The new measure should return the sum of the Reseller Sales Amount measure using the YTD() function and the current date member of the hierarchy of interest.
4. Add the new measure on axis 0 and execute the complete query:

```
WITH
MEMBER [Measures].[Reseller Sales YTD] AS
    Sum( YTD( [Date].[Calendar Weeks].CurrentMember ),
        [Measures].[Reseller Sales Amount] )
SELECT
    { [Measures].[Reseller Sales Amount],
      [Measures].[Reseller Sales YTD] } ON 0,
    { [Date].[Calendar Weeks].[Calendar Week].MEMBERS } ON 1
FROM
    [Adventure Works]
```

5. The result will include the second column, the one with the YTD values. Notice how the values in the second column increase over time:

	Reseller Sales Amount	Reseller Sales YTD
Week 1 CY 2013	(null)	(null)
Week 2 CY 2013	(null)	(null)
Week 3 CY 2013	(null)	(null)
Week 4 CY 2013	(null)	(null)
Week 5 CY 2013	\$4,212,971.51	\$4,212,971.51
Week 6 CY 2013	(null)	\$4,212,971.51
Week 7 CY 2013	(null)	\$4,212,971.51
Week 8 CY 2013	(null)	\$4,212,971.51
Week 9 CY 2013	\$4,047,574.04	\$8,260,545.55
Week 10 CY 2013	(null)	\$8,260,545.55
Week 11 CY 2013	(null)	\$8,260,545.55

How it works...

The YTD() function returns the set of members from the specified date hierarchy, starting from the first date of the year and ending with the specified member. The first date of the year is calculated according to the level [Calendar Year] marked as Years type in the hierarchy [Calendar Weeks]. In our example, the YTD() value for the member **Week 11 CY 2013** is a set of members starting from **Week 1 CY 2013** and going up to that member because the upper level containing years is of the Years type.

The set is then summed up using the Sum() function and the Reseller Sales Amount measure. If we scroll down, we will see that the cumulative sum resets every year, which means that YTD() works as expected.

In this example, we used the most common aggregation function, Sum(), in order to aggregate the values of the measure throughout the calculated set. The Sum() function was used because the aggregation type of the Reseller Sales Amount measure is sum. Alternatively, we could have used the Aggregate() function instead. More information about that function can be found later in this recipe.

There's more...

Sometimes it is necessary to create a single calculation that will work for any user hierarchy of the date dimension. In that case, the solution is to prepare several YTD() functions, each using a different hierarchy, crossjoin them, and then aggregate that set using a proper aggregation function (Sum, Aggregate, and so on). However, bear in mind that this will only work if all user hierarchies used in the expression share the same year level. In other words, this will only work if there is no offset in years among them (such as exists between the fiscal and calendar hierarchies in the Adventure Works cube in 2008 R2).

Why does it have to be so? Because the cross join produces the set intersection of members on those hierarchies. Sets are generated relative to the position when the year starts. If there is offset in years, it is possible that sets won't have an intersection. In that case, the result will be an empty space. Now let us continue with a couple of working examples.

Here is an example that works for both monthly and weekly hierarchies:

```
WITH
MEMBER [Measures].[Reseller Sales YTD] AS
    Sum( YTD( [Date].[Calendar Weeks].CurrentMember ) *
        YTD( [Date].[Calendar].CurrentMember ),
        [Measures].[Reseller Sales Amount] )
SELECT
    { [Measures].[Reseller Sales Amount],
      [Measures].[Reseller Sales YTD] } ON 0,
    { [Date].[Calendar Weeks].[Calendar Week].MEMBERS } ON 1
FROM
    [Adventure Works]
```

If we replace `[Date].[Calendar Weeks].[Calendar Week].MEMBERS` with `[Date].[Calendar].[Month].MEMBERS`, the calculation will continue to work. Without the cross join part, that wouldn't be the case. Try it in order to see for yourself! Just be aware that if you slice by additional attribute hierarchies, the calculation might become wrong.

In short, there are many obstacles to getting the time-based calculation right. It partially depends on the design of the time dimension (which attributes exist, which are hidden, how the relations are defined, and so on), and partially on the complexity of the calculations provided and their ability to handle various scenarios. A better place to define time-based calculation is the MDX script. There, we can define scoped assignments, but that's a separate topic that will be covered later in Chapter 9, *Metadata-Driven Calculations*, and in the *Using utility dimension to implement time-based calculations* recipe in Chapter 7, *Business Analytics*.

In the meantime, here are some articles related to that topic:

<http://tinyurl.com/MoshaDateCalcs>

<http://tinyurl.com/DateToolDim>

Inception-To-Date calculation

A similar calculation is the inception-to-date calculation, in which we are calculating the sum of all dates up to the current member, that is, we do not perform a reset at the beginning of every year. In that case, the `YTD()` part of the expression should be replaced with this:

```
Null : [Date].[Calendar Weeks].CurrentMember
```

Using the argument in the YTD() function

The argument of the `YTD()` function is optional. When not specified, the first dimension of the `Time` type in the measure group is used. More precisely, the current member of the first user hierarchy with a level of type `Years`.

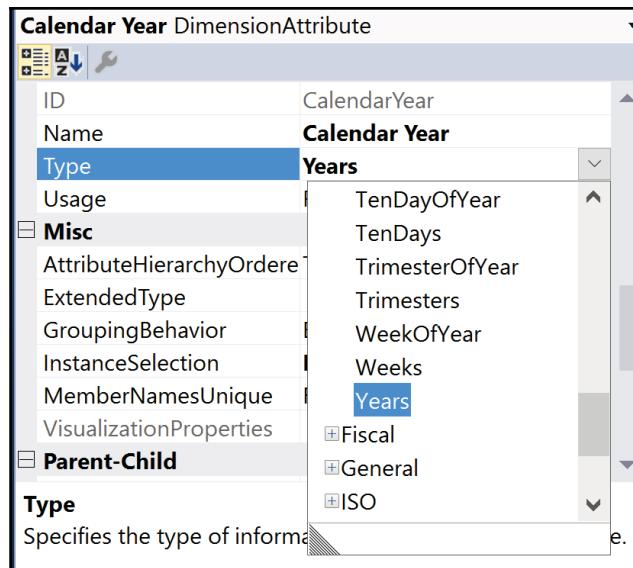

This is quite convenient in the case of a simple `Date` dimension, a dimension with a single user hierarchy. In the case of multiple hierarchies or a role-playing dimension, the `YTD()` function might not work, if we forget to specify the hierarchy for which we expect it to work.

This can be easily verified. Omit the `[Date].[Calendar Weeks].CurrentMember` part in the initial query and see that both columns return the same values. The `YTD()` function is not working anymore.

Therefore, it is best to always use the argument in the `YTD()` function.

Common problems and how to avoid them

In our example, we used the `[Date].[Calendar Weeks]` user hierarchy. That hierarchy has the level **Calendar Year** created from the same attribute. The type of attribute is `Years`, which can be verified in the **Properties** pane of SSDT:

However, the Date dimension in the Adventure Works cube has fiscal attributes and user hierarchies built from them as well. The fiscal hierarchy equivalent to [Date].[Calendar Weeks] hierarchy is the [Date].[Fiscal Weeks] hierarchy. There, the top level is named Fiscal Year, created from the same attribute. This time, the type of the attribute is Fiscal Year, not Year. If we replace the [Date].[Calendar Weeks] hierarchy by the [Date].[Fiscal Weeks] hierarchy in the WITH clause in our example query, the YTD() function will not work on the new hierarchy. It will return an error:

	Reseller Sales Amount	Reseller Sales YTD
Week 1 CY 2013	(null)	#Error
Week 2 CY 2013	(null)	#Error
Week 3 CY 2013	(null)	#Error
Week 4 CY 2013	(null)	#Error
Week 5 CY 2013	\$4,212,971.51	#Error
Week 6 CY 2013	(null)	#Error
Week 7 CY 2013	(null)	#Error
Week 8 CY 2013	(null)	#Error
Week 9 CY 2013	\$4,047,574.04	#Error
Week 10 CY 2013	(null)	#Error
Week 11 CY 2013	(null)	#Error
Week 12 CY 2013	(null)	#Error

Hover the cursor over #Error, and you will see the following error message:

Query (3, 9) By default, a year level was expected. No such level was found in the cube.

The solution is the PeriodsToDate() function.

The YTD() function is in fact a short version of the PeriodsToDate() function, which works only if the Year type level is specified in a user hierarchy. When it is not so (that is, some BI developers tend to forget to set it up correctly or in the event that the level is defined as, let us say, Fiscal Year like in this test), we can use the PeriodsToDate() function as follows:

```
MEMBER [Measures].[Reseller Sales YTD] AS  
Sum( PeriodsToDate( [Date].[Fiscal Weeks].[Fiscal Year],  
[Date].[Fiscal Weeks].CurrentMember ),  
[Measures].[Reseller Sales Amount] )
```

The `PeriodsToDate()` function might therefore be used as a safer variant of the `YTD()` function.

YTD() and future dates

It is worth noting that the value returned by a SUM-YTD combination is never empty once a value is encountered in a particular year. Only the years with no values at all will remain completely blank for all their descendants. In our example with the [Calendar Weeks] hierarchy, scrolling down to **Week 48 CY 2013**, you will see that this is the last week that has reseller sales. However, the Year-To-Date value is not empty for the rest of the weeks for year 2013, as shown in the following screenshot:

	Reseller Sales Amount	Reseller Sales YTD
Week 43 CY 2013	(null)	\$26,843,998.52
Week 44 CY 2013	\$3,314,600.78	\$30,158,599.30
Week 45 CY 2013	(null)	\$30,158,599.30
Week 46 CY 2013	(null)	\$30,158,599.30
Week 47 CY 2013	(null)	\$30,158,599.30
Week 48 CY 2013	\$3,416,234.85	\$33,574,834.16
Week 49 CY 2013	(null)	\$33,574,834.16
Week 50 CY 2013	(null)	\$33,574,834.16
Week 51 CY 2013	(null)	\$33,574,834.16
Week 52 CY 2013	(null)	\$33,574,834.16
Week 53 CY 2013	(null)	\$33,574,834.16

This can cause problems for the descendants of the member that represents the current year (and future years as well). The `NON_EMPTY` keyword will not be able to remove empty rows, meaning we will get YTD values in the future.

We might be tempted to use the `NON_EMPTY_BEHAVIOR` operator to solve this problem, but it wouldn't help. Moreover, it would be completely wrong to use it, because it is only a hint to the engine, which may or may not be used. It is not a mechanism for removing empty values, as explained in the previous chapter.

In short, we need to set some rows to null, those positioned after the member representing today's date. We will cover the proper approach to this challenge in the *Finding the last date with data* recipe.

- For the reasons explained in the last section of this recipe, you should take a look at the *Finding the last date with data* recipe

Calculating the year-over-year (YoY) growth (parallel periods)

This recipe explains how to calculate the value in a parallel period, the value for the same period in a previous year, previous quarter, or some other level in the date dimension. We are going to cover the most common scenario—calculating the value for the same period in the previous year, because most businesses have yearly cycles.

A `ParallelPeriod()` is a function that is closely related to time series. It returns a member from a prior period in the same relative position as a specified member. For example, if we specify June 2012 as the member, Year as the level, and 1 as the lag, the `ParallelPeriod()` function will return June 2013.

Once we have the measure from the prior parallel period, we can calculate how much the measure in the current period has increased or decreased with respect to the parallel period's value.

Getting ready

Start SSMS and connect to your SSAS 2016 instance. Click on the **New Query** button, and check that the target database is Adventure Works DW 2016.

In this example, we are going to use the `Date` dimension. Here is the query we will start from:

```
SELECT
    { [Measures].[Reseller Sales Amount] } ON 0,
    { [Date].[Fiscal].[Month].MEMBERS } ON 1
FROM
    [Adventure Works]
```

Once executed, the previous query returns the value of `Reseller Sales Amount` for all fiscal months.

How to do it...

Follow these steps to create a calculated measure with the YOY% calculation:

1. Add the WITH block of the query.
2. Create a new calculated measure there and name it Reseller Sales PP.
3. The new measure should return the value of the Reseller Sales Amount measure using the ParallelPeriod() function. In other words, the definition of the new measure should be as follows:

```
MEMBER [Measures].[Reseller Sales PP] As
  ( [Measures].[Reseller Sales Amount],
    ParallelPeriod( [Date].[Fiscal].[Fiscal Year], 1,
      [Date].[Fiscal].CurrentMember ) )
```

4. Specify the format string property of the new measure to match the format of the original measure. In this case, that should be the currency format.
5. Create the second calculated measure and name it Reseller Sales YoY %.
6. The definition of that measure should be the ratio of the current member's value against the parallel period member's value. Be sure to handle potential division by zero errors (see the *Handling division by zero errors* recipe in Chapter 1, *Elementary MDX Techniques*).
7. Include both calculated measures on axis 0 and execute the query, which should look as follows:

```
WITH
  MEMBER [Measures].[Reseller Sales PP] As
    ( [Measures].[Reseller Sales Amount],
      ParallelPeriod( [Date].[Fiscal].[Fiscal Year], 1,
        [Date].[Fiscal].CurrentMember ) )
    , FORMAT_STRING = 'Currency'
  MEMBER [Measures].[Reseller Sales YoY %] As
    iif( [Measures].[Reseller Sales PP] = 0, null,
      ( [Measures].[Reseller Sales Amount] /
        [Measures].[Reseller Sales PP] ) )
  , FORMAT_STRING = 'Percent'
  SELECT
    { [Measures].[Reseller Sales Amount],
      [Measures].[Reseller Sales PP],
      [Measures].[Reseller Sales YoY %] } ON 0,
    { [Date].[Fiscal].[Month].MEMBERS } ON 1
  FROM
    [Adventure Works]
```

8. The result will include two additional columns, one with the PP values and the other with the YoY change. Notice how the values in the second column repeat over time and that the YoY % ratio shows the growth over time:

	Reseller Sales Amount	Reseller Sales PP	Reseller Sales YoY %
January 2013	\$4,212,971.51	\$3,601,190.71	116.99%
February 2013	\$4,047,574.04	\$2,885,359.20	140.28%
March 2013	\$2,282,115.88	\$1,802,154.21	126.63%
April 2013	\$3,483,161.40	\$3,053,816.33	114.06%
May 2013	\$3,510,948.73	\$2,185,213.21	160.67%
June 2013	\$1,662,547.32	\$1,317,541.83	126.19%
July 2013	\$2,699,300.79	\$2,384,846.59	113.19%
August 2013	\$2,738,653.62	\$1,563,955.08	175.11%
September 2013	\$2,206,725.22	\$1,865,278.43	118.31%
October 2013	\$3,314,600.78	\$2,880,752.68	115.06%
November 2013	\$3,416,234.85	\$1,987,872.71	171.85%
December 2013	(null)	\$2,665,650.54	(null)

How it works...

The `ParallelPeriod()` function takes three arguments: a level expression, an index, and a member expression, and all three arguments are optional. The first argument indicates the level on which to look for that member's ancestor, typically the year level, like in this example. The second argument indicates how many members to go back on the ancestor's level, typically one, as in this example. The last argument indicates the member for which the function is to be applied.

Given the right combination of arguments, the function returns a member that is in the same relative position as a specified member, under a new ancestor.

The value for the parallel period's member is obtained using a tuple, which is formed with a measure and the new member. In our example, this represents the definition of the PP measure.

The growth is calculated as the ratio of the current member's value over the parallel period member's value, in other words, as a ratio of two measures. In our example, that was the YoY % measure.

In our example, we have also taken care of a small detail, setting the FORMAT_STRING to Percent.

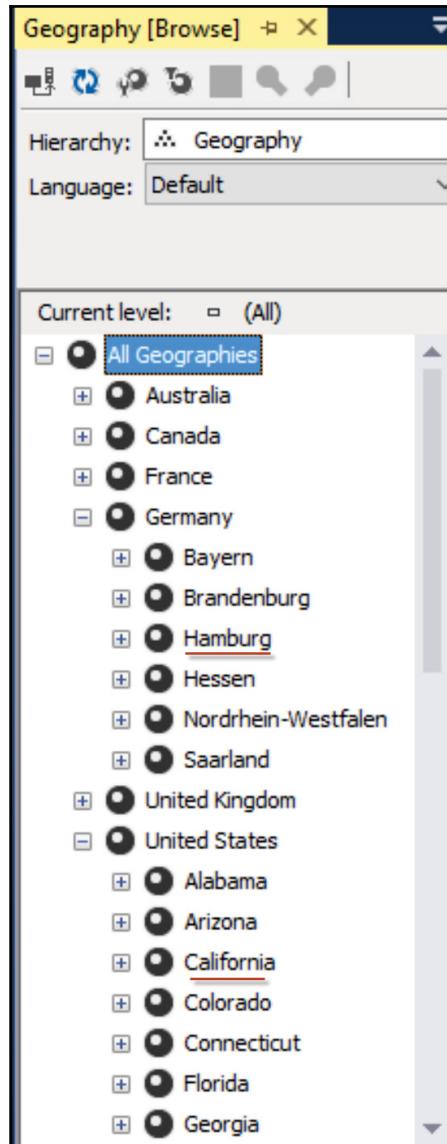

There's more...

The ParallelPeriod() function is very closely related to time series, and it is typically used on date dimensions. However, it can be used on any type of dimension. For example, this query is perfectly valid:

```
SELECT
    { [Measures].[Reseller Sales Amount] } ON 0,
    { ParallelPeriod( [Geography].[Geography].[Country],
                      2,
                      [Geography].[Geography].[State-Province]
                        .&[CA]&[US] ) } ON 1
FROM
    [Adventure Works]
```

The query returns **Hamburg** on rows, which is the third state-province in the alphabetical list of state-provinces under **Germany**. **Germany** is two countries back from the **United States**, whose member **California**, used in this query, is the third state-province underneath that country in the **[Geography] . [Geography]** user hierarchy.

We can verify this by browsing the **Geography** user hierarchy in the **Geography** dimension in SQL Server Management Studio, as shown in the following screenshot. The **United Kingdom**, one member back from the **United States**, has only one state-province: **England**. If we change the second argument to one instead, we will get nothing on the rows because there is no third state-province under the **United Kingdom**. Feel free to try it:

All arguments of the `ParallelPeriod()` function are optional. When not specified, the first dimension of the `Time` type in the measure group is used, more precisely, the previous member of the current member's parent. This can lead to unexpected results as discussed in the previous recipe. Therefore, it is recommended that you use all the arguments of the `ParallelPeriod()` function.

ParallelPeriod is not a time-aware function

The `ParallelPeriod()` function simply looks for the member from the prior period based on its relative position to its ancestor. For example, if your hierarchy is missing the first six months in the year 2012, for member January 2013, the function will find July 2012 as its parallel period (lagging by 1 year) because July is indeed the first month in the year 2012.

This is exactly the case in Adventure Works DW SSAS prior to 2012.

You can test the following scenario in Adventure Works DW SSAS 2008 R2.

In our example, we used the `[Date].[Fiscal]` user hierarchy. That hierarchy has all 12 months in every year, which is not the case with the `[Date].[Calendar]` user hierarchy where there is only 6 months in the first year. This can lead to strange results. For example, if you search-replace the word `Fiscal` with the word `Calendar` in the query we used in this recipe, you will get this as the result:

	Internet Sales Amount	Internet Sales PP	Internet Sales YoY %
July 2005	\$473,388.16	(null)	(null)
August 2005	\$506,191.69	(null)	(null)
September 2005	\$473,943.03	(null)	(null)
October 2005	\$513,329.47	(null)	(null)
November 2005	\$543,993.41	(null)	(null)
December 2005	\$755,527.89	(null)	(null)
January 2006	\$596,746.56	\$473,388.16	126.06%
February 2006	\$550,816.69	\$506,191.69	108.82%
March 2006	\$644,135.20	\$473,943.03	135.91%
April 2006	\$663,692.29	\$513,329.47	129.29%
May 2006	\$673,556.20	\$543,993.41	123.82%
June 2006	\$676,763.65	\$755,527.89	89.57%
July 2006	\$500,365.16	(null)	(null)
August 2006	\$546,001.47	(null)	(null)
September 2006	\$350,466.99	(null)	(null)
October 2006	\$415,390.23	(null)	(null)
November 2006	\$335,095.09	(null)	(null)
December 2006	\$577,314.00	(null)	(null)

Notice how the values are incorrect for the year 2006. That's because the `ParallelPeriod()` function is not a time-aware function; it merely does what it is designed for, taking the member that is in the same relative position. Gaps in your time dimension are another potential problem. Therefore, always make the complete date dimensions, with all 12 months in every year and all dates in them, not just working days or similar shortcuts. Remember, Analysis Services isn't doing the date math. It's just navigating using the member's relative position. Therefore, make sure you have laid a good foundation for that.

However, that is not always possible. There is an offset of 6 months between fiscal and calendar years, meaning if you want both of them as date hierarchies, you have a problem; one of them will not have all of the months in the first year.

The solution is to test the current member in the calculation and to provide a special logic for the first year, fiscal or calendar; the one that does not have all months in it. This is most efficiently done with a scope statement in the MDX script. This edition of the book has added a brand new Chapter 9, *Metadata-Driven Calculations* that provides many practical examples on how to use scope statements in MDX script.

Another problem in calculating the YoY value is leap years. One possible solution for that is presented in this blog article: <http://tinyurl.com/LeapYears>.

See also

- The `ParallelPeriod()` function operates on a single member. However, there are times when we will need to calculate the parallel period for a set of members. The *Calculating parallel periods for multiple members in a set* and *Calculating parallel periods for multiple members in a slicer* recipes deal with this more complex request.

Calculating moving averages

The moving average, also known as the rolling average, is a statistical technique often used in events with unpredictable short-term fluctuations in order to smooth their curve and to visualize the pattern of behavior.

The key to get the moving average is to know how to construct a set of members up to and including a specified member, and to get the average value over the number of members in the set.

In this recipe, we are going to look at two different ways to calculate moving averages in MDX.

Getting ready

Start SQL Server Management Studio and connect to your SSAS 2016 instance. Click on the **New Query** button and check that the target database is Adventure Works DW 2016.

In this example, we are going to use the `Date` hierarchy of the `Date` dimension. Here is the query we will start from:

```
SELECT
    { [Measures].[Internet Order Count] } ON 0,
    { [Date].[Date].[Date].MEMBERS } ON 1
FROM
    [Adventure Works]
```

Execute it. The result shows the count of Internet orders for each date in the `[Date].[Date]` attribute hierarchy. Our task is to calculate the simple moving average (SMA) for dates in the year 2008 based on the count of orders in the previous 30 days.

How to do it...

We are going to use the `LastPeriods()` function with a 30 day moving window, and a member expression, `[Date].[Date].CurrentMember`, as two parameters, and also the `Avg()` function, to calculate the moving average of Internet order count in the last 30 days.

Follow these steps to calculate moving averages:

1. Add the `WHERE` part of the query and put the year 2014 inside using any available hierarchy.
2. Add the `WITH` part and define a new calculated measure. Name it `SMA 30`.
3. Define that measure using the `Avg()` and `LastPeriods()` functions.
4. Test to see whether you get a managed query similar to this. If so, execute it:

```
WITH
MEMBER [Measures].[SMA 30] AS
Avg( LastPeriods( 30, [Date].[Date].CurrentMember ),
[Measures].[Internet Order Count] )
SELECT
{ [Measures].[Internet Order Count],
[Measures].[SMA 30] } ON 0,
```

```
{ [Date].[Date].[Date].MEMBERS } ON 1  
FROM  
[Adventure Works]  
WHERE  
( [Date].[Calendar Year].&[2014] )
```

5. The second column in the result set will represent the simple moving average based on the last 30 days.
6. Our final result will look like the following screenshot:

	Internet Order Count	SMA 30
January 1, 2014	24	70
January 2, 2014	29	68
January 3, 2014	30	66
January 4, 2014	29	64
January 5, 2014	51	63
January 6, 2014	26	62
January 7, 2014	28	61
January 8, 2014	33	59
January 9, 2014	30	58
January 10, 2014	19	57
January 11, 2014	33	54
January 12, 2014	34	53
January 13, 2014	32	52
January 14, 2014	39	50
January 15, 2014	29	49

How it works...

The moving average is a calculation that uses the moving window of N items for which it calculates the statistical mean, that is, the average value. The window starts with the first item and then progressively shifts to the next one until the whole set of items is passed.

The function that acts as the moving window is the `LastPeriods()` function. It returns N items; in this example, 30 dates. That set is then used to calculate the average orders using the `Avg()` function.

Note that the number of members returned by the `LastPeriods()` function is equal to the span, 30, starting with the member that lags 30-1 from the specified member expression, and ending with the specified member.

There's more...

Another way of specifying what the `LastPeriods()` function does is to use a range of members with a range-based shortcut. The last member of the range is usually the current member of the hierarchy on an axis. The first member is the *N-1th* member moving backwards on the same level in that hierarchy, which can be constructed using the `Lag(N-1)` function.

The following expression employing the `Lag()` function and a range-based shortcut is equivalent to the `LastPeriods()` function in the preceding example:

```
[Date].[Date].CurrentMember.Lag(29) : [Date].[Date].CurrentMember
```

Note that the members returned from the range-based shortcut are inclusive of both the starting member and the ending member.

We can easily modify the moving window scope to fit different requirements. For example, in case we need to calculate a 30-day moving average up to the previous member, we can use this syntax:

```
[Date].[Date].CurrentMember.Lag(30) : [Date].[Date].PrevMember
```

The `LastPeriods()` function is not on the list of optimized functions on this web page: <http://tinyurl.com/Improved2008R2>. However, tests show no difference in duration with respect to its range alternative. Still, if you come across a situation where the `LastPeriods()` function performs slowly, try its range alternative.

Finally, in the event that we want to parameterize the expression (for example, to be used in SQL Server Reporting Services), these would be generic forms of the previous expressions:

```
[Date].[Date].CurrentMember.Lag( @span - @offset ) :  
[Date].[Date].CurrentMember.Lag( @offset )
```

And;

```
LastPeriods( @span, [Date].[Date].CurrentMember.Lag( @offset ) )
```

The @span parameter is a positive value that determines the size of the window. The @offset parameter determines how much the right side of the window has moved from the current member's position. This shift can be either a positive or negative value. The value of zero means there is no shift at all, the most common scenario.

Other ways to calculate the moving averages

The simple moving average (SMA) is just one of many variants of calculating the moving averages. A good overview of a possible variant can be found in Wikipedia:

<http://tinyurl.com/WikiMovingAvg>.

MDX examples of other variants of moving averages can be found in *Mosha Pasumansky's* blog article:

<http://tinyurl.com/MoshaMovingAvg>.

Moving averages and the future dates

It is worth noting that the value returned by the moving average calculation is not empty for dates in the future because the window is looking backwards, so that there will always be values for future dates. This can be easily verified by scrolling down in our example using the `LastPeriods()` function, as shown in the following screenshot:

	Internet Order Count	SMA 30
January 24, 2014	29	35
January 25, 2014	32	33
January 26, 2014	31	32
January 27, 2014	23	31
January 28, 2014	40	31
January 29, 2014	(null)	31
January 30, 2014	(null)	31
January 31, 2014	(null)	31
February 1, 2014	(null)	31
February 2, 2014	(null)	32

In this case, the `NON EMPTY` keyword will not be able to remove empty rows.

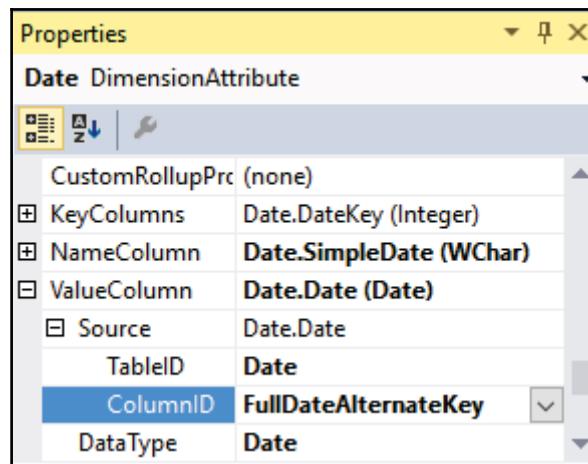

We might be tempted to use `NON_EMPTY_BEHAVIOR` to solve this problem but it would not help. Moreover, it would be completely wrong, as explained in the previous chapter. We do not want to set all the empty rows to null, but only those positioned after the member representing today's date. We will cover the proper approach to this challenge in the following recipes.

Finding the last date with data

In this recipe, we are going to learn how to find the last date with data for a particular combination of members in the cube. We will start with a general calculation, not dependent on the time context, and later show how to make it time-sensitive, if required.

Getting ready

Open SQL Server Data Tools (SSDT) and then open Adventure Works DW 2016 solution. Double-click on the **Date** dimension found in the Solution Explorer. Select the **Date** attribute and locate the property **ValueColumn** at the bottom of the **Properties** pane:

There is a value in that property. Column **FullDateAlternateKey**, of the **DataType**, is specified as the **ValueColumn** of the key attribute property, the **Date** attribute. This check is important because without that property filled correctly, this recipe won't work.

Next, start SQL Server Management Studio and connect to your SSAS 2016 instance. Click on the **New Query** button and check that the target database is Adventure Works DW 2016.

In this example, we're going to use the `Date` hierarchy of the `Date` dimension. Here is the query we will start from:

```
SELECT
    { [Measures].[Internet Order Count] } ON 0,
    { [Date].[Date].[Date].MEMBERS } ON 1
FROM
    [Adventure Works]
```

Execute it, and then scroll down to the end. By scrolling up again, try to identify the last date with data. It should be the **January 28, 2014** date, as highlighted in the following screenshot:

	Internet Order Count
January 23, 2014	32
January 24, 2014	29
January 25, 2014	32
January 26, 2014	31
January 27, 2014	23
January 28, 2014	40
January 29, 2014	(null)
January 30, 2014	(null)
January 31, 2014	(null)

Now let's see how we can get this automatically, as the result of a calculation.

How to do it...

Follow these steps to create a calculated measure that returns the last date with data:

1. Add the `WITH` part of the query.
2. Create a new calculated measure there and name it `Last_date`.
3. Use the `Max()` function with `Date` attribute members as its first argument.
4. The second argument should be the `MemberValue()` function applied on the current member of the `Date.Date.Date` hierarchy, but only if the value of the `Internet order count` measure is not empty or 0.

5. Add the Last date measure on the columns axis.
6. Put the Promotion.Promotion hierarchy on rows instead.
7. Run the query, which should look as follows:

```
WITH
MEMBER [Measures].[Last date] AS
    Max( [Date].[Date].[Date].MEMBERS,
        iif( [Measures].[Internet Order Count] = 0,
            null,
            [Date].[Date].CurrentMember.MemberValue
        )
    )
SELECT
{ [Measures].[Internet Order Count],
[Measures].[Last date] } ON 0,
{ [Promotion].[Promotion].MEMBERS } ON 1
FROM
[Adventure Works]
```

8. The result will show the last date of Internet orders for each promotion, as shown in the following screenshot:

	Internet Order Count	Last date
All Promotions	27,659	2014/01/28
No Discount	27,119	2014/01/28
Volume Discount 11 to 14	2,075	2013/12/28
Volume Discount 15 to 24	(null)	(null)
Volume Discount 25 to 40	(null)	(null)
Volume Discount 41 to 60	(null)	(null)
Volume Discount over 60	(null)	(null)
Mountain-100 Clearance Sale	(null)	(null)
Sport Helmet Discount-2002	(null)	(null)
Road-650 Overstock	(null)	(null)
Mountain Tire Sale	(null)	(null)
Sport Helmet Discount-2003	(null)	(null)
LL Road Frame Sale	(null)	(null)
Touring-3000 Promotion	20	2013/03/27
Touring-1000 Promotion	13	2013/03/22
Half-Price Pedal Sale	(null)	(null)
Mountain-500 Silver Clearance Sale	(null)	(null)

How it works...

The **Date** dimension in the Adventure Works DW 2016 database is designed in such a way that we can conveniently use the `MemberValue()` function on the `Date` attribute in order to get the date value for each member in that hierarchy. This best practice act allows us to use that value inside the `Max()` function and hence get the member with the highest value, the last date.

The other thing we must do is to limit the search only to dates with Internet orders. The inner `iif()` statement, which provides null for dates with no Internet orders, not only takes care of that, but also makes the set sparse and therefore allows for block-mode evaluation of the outer `Max()` function.

Since the data type of the `ValueColumn` property is defined as `Date` for the `Date` attribute, the result of the `MemberValue()` function is a typed value, that is, a date type. The role of this date type is twofold in this recipe. One, it allows us to use the member value inside the `Max()` function, which returns the maximum value representing the last date. Two, it allows the calculated measure, `[Last date]`, to be nicely formatted as a date without any additional coding.

Finally, the outer `Max()` function evaluates all the date values returned from the `MemberValue()` function over the set of all members in the `Date` hierarchy, and returns the maximum date value, which represents the last date.

In the event that there was no `ValueColumn` property defined on the `Date.Date` attribute, we could use the `Name`, `Caption`, or some other property to identify the last date or to use it in further calculations.

There's more...

In the previous example, the `Max()` function was used on all dates in the `Date.Date` hierarchy. As such, it is relatively inflexible. This means that it won't react to other hierarchies of the same dimension on axes, which would normally reduce that set of dates. In other words, there are situations when the expression has to be made context-sensitive so that it changes in respect to other hierarchies of the same dimension. How do we achieve that? Using the `EXISTING` operator in front of the set!

For example, let's run the following query:

```
WITH  
MEMBER [Measures].[Last date] AS  
    Max( [Date].[Date].[Date].MEMBERS,
```

```
iif( [Measures].[Internet Order Count] = 0,
    null,
    [Date].[Date].CurrentMember.MemberValue
)
)
MEMBER [Measures].[Last existing date] AS
Max( EXISTING [Date].[Date].[Date].MEMBERS,
    iif( [Measures].[Internet Order Count] = 0,
        null,
        [Date].[Date].CurrentMember.MemberValue
    )
)
SELECT
{ [Measures].[Internet Order Count],
[Measures].[Last date],
[Measures].[Last existing date] } ON 0,
{ [Date].[Calendar Year].MEMBERS } ON 1
FROM
[Adventure Works]
WHERE
( [Sales Territory].[Sales Territory Country].&[France] )
```

Now values in the second column (the `Last date` measure) will all be the same showing `2014/01/26`. On the other hand, values in the third column represent the last date for which we have Internet orders for each calendar year on the rows axis, and therefore will differ, as seen in this screenshot:

	Internet Order Count	Last date	Last existing date
All Periods	2,484	2014/01/26	2014/01/26
CY 2005	(null)	2014/01/26	(null)
CY 2006	(null)	2014/01/26	(null)
CY 2007	(null)	2014/01/26	(null)
CY 2008	(null)	2014/01/26	(null)
CY 2009	(null)	2014/01/26	(null)
CY 2010	1	2014/01/26	2010/12/29
CY 2011	140	2014/01/26	2011/12/28
CY 2012	359	2014/01/26	2012/12/31
CY 2013	1,917	2014/01/26	2013/12/31
CY 2014	67	2014/01/26	2014/01/26

Those two types of calculation represent different things and should be used in the right context. In other words, if there is a need to get the last date no matter what, then that's a variant without the EXISTING part. In all other cases, the EXISTING keywords should be used.

One thing is important to remember: the use of the EXISTING keyword slows down the performance of the query. That is the cost we have to pay for having flexible calculations.

See also

- The next recipe, *Getting values on the last date with data*, is relevant for this recipe because it shows how to return the value of measures on the last date with data

Getting values on the last date with data

In this recipe we are going to learn how to get the value of a measure on the last date with data. If you haven't read the previous recipe, do so before reading this one as this recipe continues where the previous recipe stopped.

Getting ready

Start SQL Server Management Studio and connect to your SSAS 2016 instance. Click on the **New Query** button and check that the target database is Adventure Works DW 2016.

In this example, we are going to use the simplified version of the query from the previous chapter, simplified in the sense that it has only one measure, the time-sensitive measure:

```
WITH
MEMBER [Measures].[Last existing date] AS
    Max( EXISTING [Date].[Date].[Date].MEMBERS,
        iif( [Measures].[Internet Order Count] = 0,
            null,
            [Date].[Date].CurrentMember.MemberValue
        )
    )
SELECT
    { [Measures].[Internet Order Count],
        [Measures].[Last existing date] } ON 0,
    { [Date].[Calendar Year].MEMBERS } ON 1
FROM
```

```
[Adventure Works]
WHERE
( [Sales Territory].[Sales Territory Country].&[France] )
```

The following screenshot shows the result of query execution:

All Periods	Internet Order Count	Last existing date
All Periods	2,484	2014/01/26
CY 2005	(null)	(null)
CY 2006	(null)	(null)
CY 2007	(null)	(null)
CY 2008	(null)	(null)
CY 2009	(null)	(null)
CY 2010	1	2010/12/29
CY 2011	140	2011/12/28
CY 2012	359	2012/12/31
CY 2013	1,917	2013/12/31
CY 2014	67	2014/01/26

Now, let's see how to get the values on those last dates with data.

How to do it...

Follow these steps to get a measure's value on the last date with data:

1. Remove the `Last existing date` calculated measure from the `WITH` part of the query and from the columns axis.
2. Define a new calculated measure and name it `Value_N`.
3. The definition of this new measure should be a tuple with two members, members we will identify or build in the following steps.
4. Use the `Internet Order Count` measure as one of the members in the tuple.
5. The other part of the tuple should be an expression, which in its inner part has the `NonEmpty()` function applied over members of the `Date.Date` hierarchy and the `Internet Order Count` measure.

6. Use the EXISTING operator in front of the NonEmpty() function.
7. Extract the last member of that set using the Tail() function.
8. Convert the resulting set into a member using the Item() function.
9. The final query should look as follows:

```
WITH
MEMBER [Measures].[Value N] AS
    ( Tail( EXISTING
        NonEmpty( [Date].[Date].[Date].MEMBERS,
                  [Measures].[Internet Order Count] ),
        1
    ).Item(0),
      [Measures].[Internet Order Count] )
SELECT
    { [Measures].[Internet Order Count],
      [Measures].[Value N] } ON 0,
    { [Date].[Calendar Year].MEMBERS } ON 1
FROM
    [Adventure Works]
WHERE
    ( [Sales Territory].[Sales Territory Country].&[France] )
```

10. Once executed, the result will show values of the Internet Order Count measure on the last dates with data, as visible in the following screenshot:

	Internet Order Count	Value N
All Periods	2,484	1
CY 2005	(null)	(null)
CY 2006	(null)	(null)
CY 2007	(null)	(null)
CY 2008	(null)	(null)
CY 2009	(null)	(null)
CY 2010	1	1
CY 2011	140	1
CY 2012	359	3
CY 2013	1,917	1
CY 2014	67	1

How it works...

The value of the last date with data is calculated from scratch. First, we have isolated dates with orders using the `NonEmpty()` function. Then we have applied the `EXISTING` operator in order to get dates relevant to the existing context. The `Tail()` function was used to isolate the last date in that set, while the `Item()` function converts that one-member set into a member.

Once we have the last date with data, we can use it inside the tuple with the measure of our interest, in this case, the Internet Order Count measure, to get the value in that coordinate.

There's more...

The `NonEmpty()` function we used in the earlier query for calculating the last date with data is not the only approach. We have several more options here, all of which make use of the `Last existing date` calculated measure from our previous recipe, *Finding the last date with data*, in which we have defined it as:

```
MEMBER [Measures].[Last existing date] AS  
    Max( EXISTING [Date].[Date].MEMBERS,  
        IIF( [Measures].[Internet Order Count] = 0,  
            null,  
            [Date].[Date].CurrentMember.MemberValue  
        )  
    )
```

Let's focus on a couple of other options that make use of the `Last existing date` calculated measure.

One approach is to use the `Filter()` function on all dates in order to find the one that has the same `MemberValue` as calculated in the `Last existing date` measure. However, that is the worst approach, the slowest one, and it shouldn't be used. The reason why it's slow is because the `Filter()` function needs to iterate over the complete set of dates in every cell in order to isolate a single date, the last one with data.

Since we already know the date we need, that is, the calculated `Last existing date` measure, you might think that we can simply form a tuple by putting together the `Last existing date` with `[Measures].[Internet Order Count]`. This will not work because `Last existing date` is a value, not a member. We cannot simply put a value in a tuple; we need a member because tuples are formed from members, not values.

The other approach is based on the idea that we might be able to convert that value into a member. Conversion can be done using the `StrToMember()` function, with the `CONSTRAINED` flag provided in it to enable faster execution of that function. Here are two expressions that work for the `Date` dimension in Adventure Works; they return the same result as shown in the previous screenshot:

```
MEMBER [Measures].[Value SN] AS
    iif( IsEmpty([Measures].[Last existing date]), null,
        ( StrToMember( '[Date].[Date].[' +
            Format( [Measures].[Last existing date],
                "MMMM dd, yyyy" ) + ']', CONSTRAINED ),
            [Measures].[Internet Order Count] ) )
MEMBER [Measures].[Value SK] AS
    iif( IsEmpty([Measures].[Last existing date]), null,
        ( StrToMember( '[Date].[Date].&[' +
            Format( [Measures].[Last existing date],
                "yyyyMMdd" ) + ']', CONSTRAINED ),
            [Measures].[Internet Order Count] ) )
```

The first calculated measure (with the `SN` suffix) builds the member using its name, and the second one (with the `SK` suffix) using its key. The `S` stands for string-based solution; the `N` in the first solution in this recipe stands for nonempty-based solution.

Both expressions make use of the `Format()` function and apply the appropriate format for the date returned by the `Last existing date` calculated measure.

Since there might not be any date in a particular context, the `IIF()` function is used to return null in those situations, otherwise the appropriate tuple is formed and its value is returned as the result of the expression.

Formatting members on the Date dimension properly

If you drag and drop any member from the `Date.Date.Date` level in the **Query Editor**, you will see its unique name. In case of the Adventure Works cube, the unique name will look as follows:

```
[Date].[Date].&[20130701]
```

This is the key-based unique name for members on the `Date` dimension. To build a string, all you have to do is replace the part with the day, month, and year with the appropriate tokens in the format string. This web page might help in that: <http://tinyurl.com/FormatDate>.

For the name-based member unique names you need to analyze the name of the member in the cube structure and match it with appropriate tokens in the format string. For the preceding key-based date member, the equivalent name-based member unique name is: [Date]. [Date]. [July 1, 2013].

Optimizing time-non-sensitive calculations

Remember that in the event that you do not need a time-sensitive calculation, a calculation which evaluates the dates in each context (and hence is naturally slower because of that), you can use the same expressions provided in this recipe. Just remove the EXISTING operator in them.

Calculating today's date using the string functions

Calculating today's date is one of those problems every BI developer encounters sooner or later. It is also a repeatedly asked question on Internet forums; probably because books do not cover this topic at all, or at least, not with concrete examples.

The Date dimension in the Adventure Works DW 2016 SSAS database has dates only up to December 31, 2014. If we are creating a current date expression, that is, after December 31, 2014, then the expression will not be valid. To overcome this little inconvenience, we will use string functions to only get the day and month of the current date, with the year being shifted to any year we need to.

In fact, this approach can not only explain the concept well, but also is generic enough so that you can apply it in your own SSAS database.

We will cover this intriguing topic in three recipes.

This recipe demonstrates the most intuitive technique of doing it, that is, generating today's date as a string and then converting that string into a dimension member. The other two recipes, following immediately after this one, show some not-so-intuitive, but nevertheless perfectly valid and often better ways of performing the same thing. You are advised to read them all in order to get an overview of the possibilities.

Getting ready

Start SQL Server Management Studio and connect to your SSAS 2016 instance. Click on the **New Query** button and check that the target database is Adventure Works DW 2016.

Execute the following query:

```
SELECT
    { } ON 0,
    { [Date].[Calendar].[Date].MEMBERS } ON 1
FROM
    [Adventure Works]
```

In this example, we are using the `Calendar` hierarchy of the `Date` dimension. The result contains all the dates on rows and nothing on the columns. We have explained this type of query in the first recipe of the first chapter.

Building the correct string for an Adventure Works cube is not a problem. Building the correct string for any database is almost impossible. The string has to be precise or it won't work. That's why we'll use the step-by-step approach here. We'll also highlight the important points for each step. Additionally, a step-by-step way is much easier to debug by visualizing which step is not calculating correctly. Hence, achieving the correct string for today's date becomes faster.

If you scroll down the results, you will notice that there are only dates up to and including December 2014 and there is no date after that. As the last year that has sales amounts for the full year is 2013, we're going to build the current date for that year, for this recipe as well as for the next two recipes.

We'll also include a switch for shifting years, which will allow you to apply the same recipe in any database.

How to do it...

Follow these steps to calculate today's date using the VBA date time function `Now()` and string function `Format()`, and then finally using the `StrToMember()` function to convert the string to a member on the `Date` dimension:

1. Add the `WITH` part in the query.

2. Define a new calculated measure using the VBA function and try to match the name of date members. In the case of the Adventure Works cube, the required definition is this: `Format(Now(), 'MMMM dd, yyyy')`.
3. Name the measure `Caption for Today` and include it in the query.
4. Execute the query and see how you matched the measure's value with the name of each member on the rows. If it doesn't match, try to fix the format to fit your regional settings. This link provides detailed information about what each token represents: <http://tinyurl.com/FormatDate>
5. Add the second calculated measure with the following definition:
`[Date]. [Calendar].CurrentMember.UniqueName`
6. Name it `Member's Unique Name` and include it in the query.
7. Execute the query and notice the part of the measure's value that is not constant and that is changed in each row. Try to detect what the part is built from in terms of years, months, and dates or how it relates in general to dates on rows.
8. Add the third calculated measure by formatting the result of the `Now()` function based on the discoveries you made in the previous step. In other words, this: `Format(Now(), 'yyyyMMdd')`, because unique names are built using the `yyyyMMdd` sequence.
9. Name it `Key for Today` and include it in the query.
10. Execute the query. The value should repeat in every row, giving you the current date formatted as `yyyyMMdd`.
11. In case of a database with no today's date in the `Date` dimension, such is the case here, add the fourth calculated measure. This measure should replace the year part with another year, already present in the `Date` dimension. That should be the year with all dates; otherwise, you'll get an error in subsequent steps of this recipe. The definition of that measure in the case of the Adventure Works cube is this: `'2013' + Right([Measures].[Key for Today], 4)`.
12. Name it `Key for Today (AW)` and include it in the query.
13. Execute the query and find the row where that same key can be found as a part of the measure `Member's Unique Name`. If you can, that means you're doing everything fine so far.

14. Add the fifth calculated measure, name it Today (string) and define it by concatenating the fixed part of the unique name with the variable part defined as the Key for Today or Key for Today (AW) measure, depending on whether you have or don't have today's date in your Date dimension. In this example, we'll use the latter because Adventure Works doesn't have it. This is the definition of the measure: '[Date].[Calendar].[Date].&[' + [Measures].[Key for Today (AW)] + ']'.
15. Include that fifth measure as well in the query and execute it. In that particular row mentioned earlier, the value of this measure should match completely to the value of the measure Member's Unique Name.
16. Add a calculated set. Name it Today and define it using the StrToMember() function with the CONSTRAINED flag.
17. Execute the query. The set you just made represents today's date and can be used in all further calculations you make.
18. The final query is as follows:

```
WITH
MEMBER [Measures].[Caption for Today] AS
    Format(Now(), 'MMMM dd, yyyy')
MEMBER [Measures].[Member's Unique Name] AS
    [Date].[Calendar].CurrentMember.UniqueName
MEMBER [Measures].[Key for Today] AS
    Format(Now(), 'yyyyMMdd')
MEMBER [Measures].[Key for Today (AW)] AS
    '2013' + Right([Measures].[Key for Today], 4)
MEMBER [Measures].[Today (string)] AS
    '[Date].[Calendar].[Date].&[' +
    [Measures].[Key for Today (AW)] + ']'
SET [Today] AS
StrToMember( [Measures].[Today (string)], CONSTRAINED )
SELECT
    { [Measures].[Caption for Today],
        [Measures].[Member's Unique Name],
        --[Measures].[Key for Today],
        [Measures].[Key for Today (AW)],
        [Measures].[Today (string)] } ON 0,
    { [Date].[Calendar].[Date].MEMBERS } ON 1
FROM
    [Adventure Works]
```

19. The result of your query should look like the following screenshot. There is one single row in which the Today (string) measure and the Member's Unique Name measure matches exactly, as visible in the screenshot. This row will differ from the row in your result since you are running the query on a different date. But you should nevertheless have such a row if you've followed the instructions carefully:

	Caption for Today	Member's Unique Name	Key for Today (AW)	Today (string)
July 2, 2013	July 04, 2016	[Date].[Calendar].[Date].&[20130702]	20130704	[Date].[Calendar].[Date].&[20130704]
July 3, 2013	July 04, 2016	[Date].[Calendar].[Date].&[20130703]	20130704	[Date].[Calendar].[Date].&[20130704]
July 4, 2013	July 04, 2016	[Date].[Calendar].[Date].&[20130704]	20130704	[Date].[Calendar].[Date].&[20130704]
July 5, 2013	July 04, 2016	[Date].[Calendar].[Date].&[20130705]	20130704	[Date].[Calendar].[Date].&[20130704]
July 6, 2013	July 04, 2016	[Date].[Calendar].[Date].&[20130706]	20130704	[Date].[Calendar].[Date].&[20130704]
July 7, 2013	July 04, 2016	[Date].[Calendar].[Date].&[20130707]	20130704	[Date].[Calendar].[Date].&[20130704]
July 8, 2013	July 04, 2016	[Date].[Calendar].[Date].&[20130708]	20130704	[Date].[Calendar].[Date].&[20130704]

July 10, 2013	July 04, 2016	[Date].[Calendar].[Date].&[20130710]	20130704	[Date].[Calendar].[Date].&[20130704]
July 11, 2013	July 04, 2016	[Date].[Calendar].[Date].&[20130711]	20130704	[Date].[Calendar].[Date].&[20130704]
July 12, 2013	July 04, 2016	[Date].[Calendar].[Date].&[20130712]	20130704	[Date].[Calendar].[Date].&[20130704]

How it works...

Basically, that's the query you get by following the step-by-step instructions from the earlier example, with only one difference the Key for Today measure is intentionally left out of the query, so that the result can fit the book size. You can leave it as is in your query, uncommented, to see its values.

The Caption for Today measure is there only to make you practice building the format string for dates; it has no significance for the final calculation. MMMM displays the full month name (that is, **March**), dd displays the date using two digits (that is, **27**), and yyyy displays the four-digit year.

The Member's Unique Name measure is here to show how the unique member's name is built, so that we can build the exact string using today's date as a variable part of that name. Again, it is not used in the final calculation; it is here just to help build the correct string.

The `Key for Today (AW)` measure is the one that's important. It is showing that the date dimension's key is an integer in the form of `yyyyMMdd`, built according to recommended best practice. In your real projects, you might have a different key definition. There is no way of knowing in advance what the correct format should be for a particular Date dimension. Therefore, the second measure, **Member's Unique Name**, is here to enable us to identify the variable part of the unique name and to conclude how to build that part using date parts such as year, month, and date.

The measure `Today (string)` is the main part. Here, we are actually building the final string. We are concatenating the fixed part of the unique name with the `Key for Today (AW)` measure.

Finally, we built a set named `Today` from that final string using the `StrToMember()` function.

The `CONSTRAINED` flag is used for two reasons. It automatically tells us if we have made a mistake in the string-building process. It also ensures that the evaluation is faster and hence the query performance will be faster as well.

The `Today` set can now be placed on the rows, replacing the members on the `Date` level of the `Date.Calendar` hierarchy in the previous query:

```
WITH
    MEMBER [Measures].[Key for Today] AS
        Format(Now(), 'yyyyMMdd')
    MEMBER [Measures].[Key for Today (AW)] AS
        '2007' + Right([Measures].[Key for Today], 4)
    MEMBER [Measures].[Today (string)] AS
        '[Date].[Calendar].[Date].&[' +
        [Measures].[Key for Today (AW)] + ']'
    SET [Today] AS
        StrToMember( [Measures].[Today (string)], CONSTRAINED )
SELECT
    { [Measures].[Key for Today],
        [Measures].[Key for Today (AW)],
        [Measures].[Today (string)] } ON 0,
    { [Today] } ON 1
FROM
    [Adventure Works]
```

The result will have only one row. The member on the row will be today's date with a shifted year.

	Key for Today	Key for Today (AW)	Today (string)
July 4, 2013	20160704	20130704	[Date].[Calendar].[Date].&[20130704]

There's more...

A named set, contrary to a calculated member, preserves the original regular member. Regular members have a position in their level (also known as their ordinal), and they can have descendants, ancestors, and related members on other hierarchies of the same dimension. Sets can be placed in the slicer or on columns or rows where they can interact with other dimensions. Calculated members do not have these features. They are placed as the last child of a regular member they are defined on and are not related to any other members except the root member of other hierarchies of the same dimension. The idea of creating a named set for today's date, not a calculated member, has opened up a lot of possibilities for us.

Another thing worth pointing out here is that using `Now()` in a calculated member stops the use of a formula engine cache. See here for more info: [ht tp://tinyurl.com/FormulaCacheChris](http://tinyurl.com/FormulaCacheChris).

The conversion from a set made of a single member to a member, or shall we say, extraction of a single member in that set, is made relatively easy by using: `[Today].Item(0)`. Actually, we should specify `.Item(0).Item(0)`, but since there's only one hierarchy in the tuple forming that set, one `.Item(0)` is enough.

Defining new calculated measures is also easy. Today's sales measure would be defined like this: `([Today].Item(0), [Measures].[Internet Sales Amount])`.

Relative periods

The opportunity does not stop there. Once we have a named set, `Today`, for today's date, all other relative periods follow easily. Here are some examples. Again, we are defining sets, not calculated members:

```
SET [Yesterday] AS [Today].Item(0).PrevMember  
SET [This Month] AS [Today].Item(0).Parent  
SET [Prev Month] AS [This Month].Item(0).PrevMember  
SET [This Year] AS [Today].Item(0).Parent.Parent.parent.Parent  
SET [Prev Year] AS [This Year].Item(0).PrevMember  
SET [This Month Prev Year] AS [This Month].Item(0).Lag(12)
```

Moreover, you can anticipate the need for past or future relative periods and implement sets such as `[Next month]`, `[1-30 days ahead]`, `[31-60 days ahead]`, and so on.

In the case of role-playing dimensions, you can build independent sets for each role-playing dimension, that is, `[Today]` and `[Due Today]` sets, each pointing to today's system date in its own dimension (and hierarchy).

A role-playing dimension is a dimension that is used in a cube more than one time, each time for a different purpose. For example, you have a Date dimension, and you want to link it to a measure group three times to track the date that products are ordered, shipped, and received. Each role-playing dimension is joined to a fact table on a different foreign key.

Potential problems

Sets have many features that calculated members do not have. The ideal solution would be to construct the `Today` set, defining other relative periods as sets relative to the `Today` set. However, some SSAS frontend tools have problems working with sets. For example, you cannot put a named set on filters in an Excel 2007 or Excel 2010 PivotTable. If that's the case, you must be ready to make compromises by defining today's date instead as a calculated member, as explained earlier. You might also read the following recipes to find alternative solutions.

See also

- The *Calculating today's date using the MemberValue function* and *Calculating today's date using an attribute hierarchy* recipes provide an alternative solution to calculating today's date. You should read all of them in order to understand the pros and cons of each approach.

Calculating today's date using the MemberValue function

The second way to calculate today's date is by using the `MemberValue()` function. This is something we've already used in the *Finding the last date with data* recipe. In case you haven't read it yet, do so before continuing with this recipe, at least the part that shows the `ValueColumn` property.

Getting ready

Open SQL Server Data Tools (SSDT) and then open the Adventure Works DW 2016 solution. Double-click on the Date dimension found in the Solution Explorer. Select the `Date` attribute and locate the `ValueColumn` property. It should not be empty; otherwise this recipe won't work. It should have the `Date` type column from the underlying time dimension table.

How to do it...

Follow these steps to calculate today's date using the `MemberValue` function:

1. Write and execute the following query in SQL Server Management Studio connected to the same cube mentioned earlier:

```
WITH
MEMBER [Measures].[Caption for Today] AS
    Format(Now(), 'MMMM dd, yyyy')
MEMBER [Measures].[Member Value] AS
    [Date].[Calendar].CurrentMember.MemberValue
MEMBER [Measures].[MV for Today] AS
    Format(Now(), 'M/d/yyyy')
MEMBER [Measures].[MV for Today (AW)] AS
```

```
CDate( Left( [Measures].[MV for Today],  
           Len([Measures].[MV for Today]) - 4) + '2013'  
      )  
SET [Today] AS  
  Filter( [Date].[Calendar].[Date].MEMBERS,  
          [Measures].[Member Value] =  
          [Measures].[MV for Today (AW)] )  
SELECT  
  { [Measures].[Caption for Today],  
    [Measures].[Member Value],  
    [Measures].[MV for Today],  
    [Measures].[MV for Today (AW)] } ON 0,  
  { [Date].[Calendar].[Date].MEMBERS } ON 1  
FROM  
  [Adventure Works]
```

2. Then use this query to test the Today set:

```
WITH  
MEMBER [Measures].[Member Value] AS  
  [Date].[Calendar].CurrentMember.MemberValue  
MEMBER [Measures].[MV for Today] AS  
  Format(Now(), 'M/d/yyyy')  
MEMBER [Measures].[MV for Today (AW)] AS  
  CDate( Left( [Measures].[MV for Today],  
             Len([Measures].[MV for Today]) - 4) + '2013'  
        )  
SET [Today] AS  
  Filter( [Date].[Calendar].[Date].MEMBERS,  
          [Measures].[Member Value] =  
          [Measures].[MV for Today (AW)] )  
SELECT  
  { [Measures].[Member Value],  
    [Measures].[MV for Today],  
    [Measures].[MV for Today (AW)] } ON 0,  
  { [Today] } ON 1  
FROM  
  [Adventure Works]
```

3. The result should contain only a single row with today's date:

	Member Value	MV for Today	MV for Today (AW)
July 4, 2013	2013/07/04	7/4/2016	2013/07/04

How it works...

The first query is used to build the Today set in a step-by-step fashion. The first measure `Caption for Today` is used for testing the behavior of various date part tokens. The next measure `Member Value` is used to extract the `MemberValue` from each date found on the rows and is later used in the `Today's` set definition. The third measure, `MV for Today`, is the main measure. Its definition is obtained by deducing the correct format for the `MemberValue`, from the observations made by analyzing the values in the previous measure `Member Value`. The step-by-step process is explained in the previous recipe, *Calculating today's date using the string functions*.

As the Adventure Works solution doesn't have the current date, we're forced to shift it to the year 2013. The day and month stay the same. This is implemented in the fourth measure: `MV for Today (AW)`. Finally, the `Today` set is defined using a `Filter()` function, which returns only one member, the one where the `MemberValue` is equal to the `MV for Today (AW)` measure's value.

The second query is here to verify the result. It consists of three measures relevant to the set's condition and the `Today` set itself.

There's more...

The *Calculating today's date using the string functions* recipe explains how to enhance the cube design by adding relative periods in the form of additional sets. Look for the related periods section of that recipe, which is also applicable to this recipe.

Using the `ValueColumn` property in the Date dimension

Many SSAS frontends use the so-called **Time Intelligence** implementation. That means they enable the use of special MDX functions, such as `YTD()`, `ParallelPeriod()`, and others in their GUI. The availability of those functions is often determined by dimension type (has to be of the type `Date`) and by the existence of the `ValueColumn` property typed as `Date` on the key attribute of the dimension, or both. Specifically, Excel 2007 and Excel 2010 look for the latter. Be sure to check those things when you're working on your date dimension.

Here's a link to the document which explains how to design cubes for Excel: <http://tinyurl.com/DesignCubesForExcel>.

See also

- *Calculating today's date using the string functions* and *Calculating today's date using an attribute hierarchy* are the recipes that provide an alternative solution to calculating today's date. You should read both of them in order to understand the pros and cons of each approach.

Calculating today's date using an attribute hierarchy

The third way to calculate today's date is by using an attribute hierarchy. This is potentially the best way.

Instead of all the complexity with sets, strings, and other things in the previous two recipes, here we simply add a new column to the **Date** table and have the ETL maintain a flag for today's date. Then we slice by that attribute instead of using the `Now()` function in MDX. Plus, we don't have to wait to switch to *tomorrow* in MDX queries until the ETL completes and the cube is processed.

Getting ready

Open the Adventure Works DW 2016 solution in SSDT. Double-click on the Adventure Works DW data source view. Locate the **Date** dimension in the left **Tables** pane and click on it.

How to do it...

Follow these steps to calculate today's date using an attribute hierarchy:

1. Right-click on the **Date** table and select **New Named Calculation**.
2. Enter **Today** for **Column Name** and the following for the expression:

```
case when convert(varchar(8), FullDateAlternateKey, 112) =  
      convert(varchar(8), GetDate(), 112)  
      then 'Yes'  
      else 'No'  
end
```

3. Close the dialog and explore that table. No record will have Yes in the last column.
4. Since we're on Adventure Works, which doesn't have the current date, we have to adjust the calculation by shifting it to the year 2013. Define the **New Named Calculation** using this formula and name it Today AW:

```
case when convert(varchar(8), FullDateAlternateKey, 112) =  
      '2013' +  
      right(convert(varchar(8), GetDate(), 112), 4)  
  then 'Yes'  
  else 'No'  
end
```

5. Close the dialog and explore that table. You should notice that this time, one row in the year 2013 has Yes in the last column. It will be the row with the day and month the same as your system's day and month.
6. Save and close data source view.
7. Double-click on the **Date** dimension in the **Solution Explorer**.
8. Drag the **Today AW** column from the **Date** dimension table to the list of attributes on the left side. Leave the relation to the key attribute as it is flexible. This will be the only attribute of that kind in this dimension. All others should be rigid.
9. Save, deploy, and process the full **Date** dimension.
10. Double-click on the **Adventure Works** cube in the **Solution Explorer**, navigate to the **Browser** tab, and click on a button to process the cube.
11. Once it is processed, click on the **Reconnect** button and drag the **Internet Sales Amount** measure in the data part of the browser.
12. Add the **[Date] . [Calendar]** hierarchy onto the rows and expand it a few times. Notice that all the dates are here.
13. Add the **[Date] . [Today AW]** hierarchy into the slicer and uncheck the **No** member in it. Notice that the result contains only the current date. You can do the same using any other hierarchy of the **Date** dimension; all will be sliced by our new attribute.

How it works...

This recipe depends on the fact that SSAS implements the so-called `auto-exists` algorithm. The main characteristic of it is that when two hierarchies of the same dimension are found in the query, the one in the slicer automatically reduces the other on the axis so that only some of the members remain there, those for which an intersection exists.

In other words, if we put the `Yes` member into the slicer, as we did a moment ago, only those years, months, quarters, days in the week, and so on, that are valid for today's date remain, meaning the current year, month, day in the week, and so on. Only one member from each hierarchy will remain.

The same query will give different results each day. That is exactly what we wanted to achieve. The usage is fairly simple—dragging the `Yes` member into the slicer, which should be possible in any SSAS frontend.

The beauty of this solution lies not only in the elegance of creating queries, but in the fact that it is the fastest method for implementing the logic for today's date. Attribute relations offer better performance than string-handling functions and filtering.

There's more...

The solution doesn't have to stop with the `[Date].[Today AW]` hierarchy. We can add `Today` as a set in the MDX script. This time, however, we'll have to use the `Exists()` function in order to get the related members of other hierarchies. Later on, we can use navigational functions to take the right part of the hierarchy.

For example, `Today` should be defined as follows:

```
SET [Today] AS  
Exists( [Date].[Calendar].[Date].MEMBERS,  
[Date].[Today AW].&[Yes] )
```

Once we have the `Today` named set, other variants are easy to derive from it. We've covered some of them in the *Calculating today's date using the string functions* recipe.

However, be aware that named sets, when used inside aggregating functions such as `Sum()` function and others, will prevent the use of block evaluation. Here's a link to the page that talks about which things are improved and which aren't in SQL Server 2008 R2 Analysis Services: <http://tinyurl.com/Improved2008R2>.

The Yes member as a default member?

Short and simple – DON'T! This might cause problems when other hierarchies of the Date dimension are used in the slicer. That is, users of your cube might accidentally force a coordinate which does not exist.

For example, if they decide to put January in the slicer when the default Yes member implies the current quarter is not Q1, but let's say Q4, they'll get an empty result without understanding what happened and why.

A solution exists, though. In such cases, they should add the All member of the [Date].[Today AW] hierarchy in the slicer as well, to remove restrictions imposed by the default member. The question is—will you be able to explain that to your users?

A better way is to instruct them to explicitly put the Yes member in the slicer whenever required. Yes, that's extra work for them, but this way they will have control over the context and not be surprised by it.

Other approaches

There is another method and that is using many-to-many relationships. The advantage of doing this over creating new attributes on the same dimension is that we only expose a single new hierarchy, even if it is on a new dimension.

See also

- The *Calculating today's date using the string functions* and *Calculating today's date using the MemberValue function* recipes are the ones which provide an alternative solution to calculating today's date. You should read both of them in order to understand the pros and cons of each approach.

Calculating the difference between two dates

This recipe shows how to calculate the difference between two dates. We are going to use promotions as an example, and calculate the time span of a promotion, from the start date to the end date.

Getting ready

Start SQL Server Management Studio and connect to your SSAS 2016 instance. Click on the **New Query** button and check that the target database is Adventure Works DW 2016. Then execute the following query:

```
SELECT
    { [Measures].[Reseller Order Count] } ON 0,
    { [Promotion].[Start Date].[Start Date].MEMBERS *
      [Promotion].[End Date].[End Date].MEMBERS } ON 1
FROM
    [Adventure Works]
WHERE
    ( [Promotion].[Promotion Type].&[Discontinued Product] )
```

The query shows that the Discontinued Product promotion appeared twice with various time spans. Our task is to calculate how many days it lasted each time.

How to do it...

Follow these steps to calculate the difference between two dates:

1. Add the **WITH** part of the query.
2. Define two calculated measures that are going to collect the **ValueColumn** property of the **Start Date** and **End Date** hierarchies of the **Promotion** dimension.
3. Define the third calculated measure as **Number of days** using the VBA **DateDiff()** function and the two helper-calculated measures defined a moment ago. Be sure to increase the second date by one in order to calculate the duration, meaning that both start and end dates will count.
4. Include all three calculated measures on the columns and run the query, which should look like the following:

```
WITH
    MEMBER [Measures].[Start Date] AS
        [Promotion].[Start Date].CurrentMember.MemberValue
    MEMBER [Measures].[End Date] AS
        [Promotion].[End Date].CurrentMember.MemberValue
    MEMBER [Measures].[Number of days] AS
        DateDiff('d', [Measures].[Start Date],
                 [Measures].[End Date] + 1)
SELECT
    { [Measures].[Reseller Order Count],
```

```
[Measures].[Start Date],  
[Measures].[End Date],  
[Measures].[Number of days] } ON 0,  
{ [Promotion].[Start Date].[Start Date].MEMBERS *  
[Promotion].[End Date].[End Date].MEMBERS } ON 1  
FROM  
[Adventure Works]  
WHERE  
( [Promotion].[Promotion Type].&[Discontinued Product] )
```

5. Check your result. It should look as follows:

		Reseller Order Count	Start Date	End Date	Number of days
November 12, 2011	December 28, 2011	24	2011/11/12	2011/12/28	47
October 29, 2013	December 28, 2013	62	2013/10/29	2013/12/28	61

How it works...

The `DateDiff()` is a VBA function. It can also be found in T-SQL. What we have to do is specify the time interval in which we would like the difference to be expressed. In our case, we used the `d` token which corresponds to the day interval.

The duration is calculated as a difference plus one because both boundaries must be included. In the second row, it's easy to see that the 31 days in May and 30 days in June must equal 61.

There's more...

The `DateDiff()` function expects the date type items as its second and third arguments. Luckily, we had exactly the required type in the `ValueColumn` property. This can be checked by opening SSDT and analyzing the `Start Date` and `End Date` hierarchy on the `Promotion` dimension. If it weren't the case, we would have to convert them into the `Date` type and use them in the `DateDiff()` function. Here are a couple of working examples using a VBA function `CDate()` to convert a valid date expression into a `Date` type:

```
CDate( '2016-06-28' )  
  
CDate( [Promotion].[Start Date].CurrentMember.Name )
```

Dates in other scenarios

The example in this recipe highlighted a case where the two dates were found on two different hierarchies. That will not always be so. There will be situations when you'll only have a single date hierarchy or no dates at all.

There are two ways to get those dates. You can calculate them in the form of two measures as we did in this recipe or locate them on the Date hierarchy of your Date dimension.

The example illustrated in this recipe used the `DateDiff()` function, a good fit for the approach with measures since the two dates are from two different hierarchies. We should convert the value of measures (or expressions) to an appropriate date type (if it isn't already so), because the `DateDiff()` function requires dates.

The other approach is to locate the dates on one single Date hierarchy. For example, you can calculate the number of consecutive days with no change in quantity of products in the warehouse by locating a range of members on the Date hierarchy.

In that case, there is no need for the `DateDiff()` function. Simply form a range of members by employing the range-based shortcut, specifying the first date followed by a colon and then the second date. Finally, count the members in that set using the `Count()` function. Here is a working example of using the range-based shortcut and the `Count()` function:

```
Count([Date].[Date].&[20130101]:[Date].[Date].&[20130301])
```

Actually, the use of the `Count()` function might turn off block computation, so use its `Sum()` alternative:

```
Sum({<member1> : <member2>}, 1)
```

Here, `<member1>` and `<member2>` are placeholders for the range.

This will give you the same count of members in that range, but the `Sum()` function is optimized to work in block mode while `Count()` over a range is not.

When the members in that range are dates (which will typically be so), counting them will return the duration in days. If you need a different granularity (let's say the number of weeks, hours, or minutes), simply multiply the duration in days with the appropriate factor (1/7, 24, or 24*60, respectively). Additionally, for the `DateDiff()` function, you can provide the appropriate first argument. See here for options: <http://tinyurl.com/DateDiffExcel>.

The problem of non-consecutive dates

A problem will arise if dates are not consecutive, that is, if some of them are missing in your Date dimension. Here we are referring to weekends, holidays, and others which are sometimes left out of the date dimension guided by the thinking that there is no data in them, so why include them in the dimension? You should know that such a design is not recommended and the solution provided in this recipe will not work. Moreover, this will not be the only problem you'll encounter with this bad design. Therefore, consider redesigning your date dimension or look for alternative solutions listed in the *See also* section of this recipe.

Days such as weekends and holidays might not have data in them. However, leaving them out in the Date dimension is not recommended.

See also

- When the dates are close to one another, you might want to calculate the time difference instead. This is described in the following recipe, *Calculating the difference between two times*.

Calculating the difference between two times

This recipe is similar to the previous one, but here we will show how to calculate the difference in time and format the duration appropriately.

By time, we mean everything on and beneath the day granularity. What is specific about time is that all periods are proportionally divided. A day has 24 hours, an hour has 60 minutes, and a minute has 60 seconds. On the other hand, the above-day granularity is irregular days in a month vary throughout the year, and days in the year vary on leap years.

The nice thing about having proportional periods is that we can present the result in various units. For example, we can say that an event lasted for 48 hours, but we can also say 2 days. On the other hand, we can say 2 days, but we cannot say 0.06 months because a month is not a constant unit of time.

This ability to format time duration in various units will be demonstrated in the following example as well.

Getting ready

The Adventure Works database does not contain any attribute or measure that has hours, minutes, or seconds. Hence, we will create two calculated measures, one representing the start and the other representing the end of an event. Here are those measures:

```
WITH
    MEMBER [Measures].[Start Time] AS
        CDate('2013-09-18 00:40:00')
    MEMBER [Measures].[End Time] AS
        CDate('2013-09-21 10:27:00')
SELECT
    { } ON 0
FROM
    [Adventure Works]
```

How to do it...

Follow these steps to calculate the difference between two times:

1. Define a new calculated measure as a difference of two initial measures introduced earlier and name it Duration in days.
2. Put that new measure on axis 0 as a single measure and run the query, which should look as follows:

```
WITH
    MEMBER [Measures].[Start Time] AS
        CDate('2013-09-18 00:40:00')
    MEMBER [Measures].[End Time] AS
        CDate('2013-09-21 10:27:00')
    MEMBER [Measures].[Duration in days] AS
        [Measures].[End Time] - [Measures].[Start Time]
SELECT
    { [Measures].[Duration in days] } ON 0
FROM
    [Adventure Works]
```

3. The result represents the number of days between those two events.

How it works...

Each event has a starting point and an ending point. If those points in time are represented as dates, being the date type, then we can apply the simple operation of subtraction in order to get the duration of that event. In case those were not date type points, we should convert them into the date format, as shown in this example (string to date conversion using the CDate() VBA function).

There's more...

It is possible to shift the result into another time unit. For example, we can calculate the duration in hours by multiplying the initial expression with the number of hours in a day:

```
MEMBER [Measures].[Duration in hours] AS  
    ([Measures].[End Time] - [Measures].[Start Time]) * 24  
    , FORMAT_STRING = '#,##0.0'
```

Add this member into the initial query and observe the results.

Likewise, we can get the duration in minutes and seconds if required. Multiplications are by 60 and 3,600, respectively, in addition to the 24 already there for the number of hours.

Formatting the duration

Duration values can be formatted. Here's an example that shows how the original Duration in days calculation can be formatted so that the decimal part becomes displayed in a well-understood hh:mm:ss format, where hh stands for hours, mm for minutes, and ss for seconds:

```
MEMBER [Measures].[My Format] AS  
    iif([Measures].[Duration in days] > 1,  
        CStr(Int([Measures].[Duration in days])) +  
        " ",  
        "0 ")+  
    'hh:mm:ss'  
  
MEMBER [Measures].[Duration d hh:mm:ss] AS  
    ([Measures].[End Time] - [Measures].[Start Time])  
    , FORMAT_STRING = [Measures].[My Format]
```

Add this member into the initial query and observe the results.

Here is the screenshot showing all three calculated measures:

Duration in days	Duration in hours	Duration d hh:mm:ss
3.40763888888614	81.8	3 09:47:00

Notice that we have wrapped the expression for `FORMAT_STRING` in a separate calculated measure `My_Format`. The reason for this is to improve the performance through caching. Only cell values are cached; expressions on the `FORMAT_STRING` are not cached. That is why it pays off to define them in separate measures.

Examples of formatting the duration on the Web

Here are a couple of links with good examples of formatting the duration on the Web: <http://tinyurl.com/FormatDurationMosha>

<http://tinyurl.com/FormatDurationVidas>

Counting working days only

In case you are interested in counting working days only, Marco Russo, one of the reviewers of this book, presented his approach to this problem in his blog post: <http://tinyurl.com/WorkingDaysMarco>.

- When the dates are far from each other, you might want to calculate the date difference instead. This is described in the previous recipe, *Calculating the difference between two dates*.

Calculating parallel periods for multiple dates in a set

In the *Calculating the year-over-year (YoY) growth (parallel periods)* recipe, we have shown how the `ParallelPeriod()` function works and how it can be used to calculate the YoY growth. All we had to do is specify a member, ancestor's level, and an offset, and the parallel member was returned as a result.

Online Analytical Processing (OLAP) works in discrete space and therefore many functions, `ParallelPeriod()` included, expect a single member as their argument. On the other hand, relational reports are almost always designed using a date range, with `Date1` and `Date2` parameters for many relational reports. As the relational reporting has a longer tradition than the multidimensional, people are used to thinking in ranges. They expect many multidimensional reports to follow the same logic. However, operating on a range is neither easy nor efficient. A cube designed with best practices can help, by eliminating the need for ranges and increasing the performance of the cube. A well-designed cube should have various attributes on the time dimension: months, weeks, quarters, and so on. They should cover common ranges and should be used instead of a range of random dates.

However, there are times when the cube design cannot cover all the combinations and the request for reports to operate on a range is quite legitimate. The question arises—can we do the same in OLAP as in relational reporting? Can we calculate the growth based on a range of members and not just a single member?

Yes, we can. The solution in MDX exists. This recipe shows how to calculate parallel periods with multiple dates defined as a set. The next recipe shows how to deal with a more complex case—when dates are present in the slicer.

Getting ready

We are going to make a simple query. We will analyze sales by colors for a date range that starts in December and ends just before Christmas. We would like to analyze how we are doing in respect to the previous year, for the same period.

Start SQL Server Management Studio and connect to your SSAS 2016 instance. Click on the **New Query** button and check that the target database is Adventure Works DW 2016. Then execute the following query:

```
WITH  
MEMBER [Internet Sales CP] AS  
Sum( { [Date].[Calendar].[Date].&[20131201] : 
```

```
[Date].[Calendar].[Date].&[20131224] },
[Measures].[Internet Sales Amount] )
SELECT
{ [Internet Sales CP] } ON 0,
{ [Product].[Color].MEMBERS } ON 1
FROM
[Adventure Works]
```

The query has a date range. The aggregate of that range in the form of a sum is calculated in a calculated measure, which is then displayed for each color, and the total is included as the first row. The result is shown in the following screenshot:

	Internet Sales CP
All Products	\$1,622,891.90
Black	\$457,768.45
Blue	\$232,531.00
Grey	(null)
Multi	\$8,669.65
NA	\$31,495.78
Red	\$20,783.35
Silver	\$360,631.70
Silver/Black	(null)
White	\$413.54
Yellow	\$510,598.43

The calculated measure Internet Sales CP tells us the sales for each product color during December just before Christmas in the year 2013, but it is not telling us how much better or worse we are doing. What we need is the sales during the same December date range, but in the previous year. With both sales during the same date range in two different years, we can then calculate the YoY percent values.

In the *Calculating the year-over-year (YoY) growth (parallel periods)* recipe in this chapter, we have learned about the ParallelPeriod() function. Our first attempt would be to write an expression such as:

```
( ParallelPeriod( [Date].[Calendar].[Calendar Year],
1,
[Date].[Calendar].CurrentMember ),
[Measures].[Internet Sales Amount] )
```

This expression will only give us the sales for one date at a time. However, we have more than just one date. Our challenge in this recipe is to sum up the sales during all the dates in the previous year.

How to do it...

Follow these steps to calculate parallel periods for multiple dates in a set:

1. Define a new calculated measure, which returns the value for the same period, but in the previous year. Name it Internet Sales PP, where PP stands for parallel period. The expression should look as follows:

```
MEMBER [Internet Sales PP] As
    Sum({ [Date].[Calendar].[Date].&[20131201] :
        [Date].[Calendar].[Date].&[20131224] },
        ( ParallelPeriod( [Date].[Calendar].[Calendar Year],
            1,
            [Date].[Calendar].CurrentMember ),
        [Measures].[Internet Sales Amount] )
    )
, FORMAT_STRING = 'Currency'
```

2. Define another measure, Internet Sales YoY %, as a ratio of the PP measure over the CP measure. The expression should be as follows:

```
MEMBER [Internet Sales YoY %] As
    iif( [Internet Sales PP] = 0, null,
        ( [Internet Sales CP] / [Internet Sales PP] ) )
, FORMAT_STRING = 'Percent'
```

3. Add both calculated measures to the query and execute it. The query should look as follows:

```
WITH
MEMBER [Internet Sales CP] AS
    Sum( { [Date].[Calendar].[Date].&[20131201] :
        [Date].[Calendar].[Date].&[20131224] },
        [Measures].[Internet Sales Amount] )
MEMBER [Internet Sales PP] As
    Sum({ [Date].[Calendar].[Date].&[20131201] :
        [Date].[Calendar].[Date].&[20131224] },
        ( ParallelPeriod( [Date].[Calendar].[Calendar Year],
            1,
            [Date].[Calendar].CurrentMember ),
        [Measures].[Internet Sales Amount] )
```

```
)  
    , FORMAT_STRING = 'Currency'  
MEMBER [Internet Sales YoY %] As  
    iif( [Internet Sales PP] = 0, null,  
        ( [Internet Sales CP] / [Internet Sales PP] ) )  
    , FORMAT_STRING = 'Percent'  
SELECT  
    { [Internet Sales PP],  
        [Internet Sales CP],  
        [Internet Sales YoY %] } ON 0,  
    { [Product].[Color].MEMBERS } ON 1  
FROM  
    [Adventure Works]
```

4. The results show that three colors had better results than before, one had worse (red), but the overall result is almost three times better. There were also four new colors in the current season:

	Internet Sales PP	Internet Sales CP	Internet Sales YoY %
All Products	\$442,963.98	\$1,622,891.90	366.37%
Black	\$186,775.23	\$457,768.45	245.09%
Blue	(null)	\$232,531.00	(null)
Grey	(null)	(null)	(null)
Multi	(null)	\$8,669.65	(null)
NA	(null)	\$31,495.78	(null)
Red	\$99,960.12	\$20,783.35	20.79%
Silver	\$122,213.76	\$360,631.70	295.08%
Silver/Black	(null)	(null)	(null)
White	(null)	\$413.54	(null)
Yellow	\$34,014.88	\$510,598.43	1501.10%

How it works...

In order to calculate the parallel period's value for a set of members (a range in this example), we apply the same principle we use when calculating the value for the current season, summarizing the value of a measure on that range by using the `Sum()` function.

The `Sum()` function takes a set expression and a numeric expression. The calculation for the previous season differs only in the numeric expression. There, we no longer use a measure, `[Internet Sales Amount]`, but instead a tuple. That tuple is formed using the original measure, `[Internet Sales Amount]` combined with the parallel period's member. In other words, we are reaching for the value in another coordinate and summing up those values.

The calculation for the `YoY %` ratio is very straightforward. We check the division by zero and specify the appropriate format string.

There's more...

The other approach is to calculate another set, the previous season's range, and then apply the `Sum()` function. Here's the required expression:

```
MEMBER [Internet Sales PP] As
    Sum(
        Generate(
            { [Date].[Calendar].[Date].&[20071201] :
                [Date].[Calendar].[Date].&[20071224] },
            { ParallelPeriod( [Date].[Calendar]
                .[Calendar Year],
                1,
                [Date].[Calendar]
                    .CurrentMember.Item(0) )
            } ),
        [Measures].[Internet Sales Amount] )
```

Here, we are iterating on the old set using the `Generate()` function in order to shift each member of that set to its parallel member.

Note that we deliberately skipped defining any named sets for this scenario, because when they are used inside aggregating functions such as `Sum()`, they prevent the block evaluation. We should put the sets instead of named sets inside those functions.

One more thing: for measures with non-linear aggregation functions (that is, the `Distinct Count`), the `Aggregate()` function should be used instead of `Sum()`.

Parameters

The set of dates defined as a range can often be parameterized as follows:

```
{ StrToMember( @Date1, CONSTRAINED ) :  
  StrToMember( @Date2, CONSTRAINED ) }
```

This way, the query (or SSRS report) becomes equivalent to its relational reporting counterpart.

Reporting covered by design

We mentioned in the introduction to this recipe that it is often possible to improve the performance of the queries operating on a range of members by modifying the cube design. How it's done is explained in more detail in the *Using a new attribute to separate members on a level* recipe in Chapter 8, *When MDX Is Not Enough*.

See also

- The *Calculating the year-over-year (YoY) growth (parallel periods)* and *Calculating parallel periods for multiple dates in a slicer* recipes deal with a similar topic
- The `Generate()` function, very useful here, is also covered in the *Iterating on a set in order to create a new one* recipe in Chapter 2, *Working with Sets*

Calculating parallel periods for multiple dates in a slicer

In the *Calculating the year-over-year (YoY) growth (parallel periods)* recipe, we have shown how the `ParallelPeriod()` function works when there is a single member involved. In the *Calculating parallel periods for multiple dates in a set* recipe, we have shown how to do the same, but on a range of members defined in a set. This recipe presents the solution to a special case when the set of members is found in a slicer.

Getting ready

We will use the same case as in the previous recipe; we will calculate the growth in the pre-Christmas season for each color of our products.

Start SQL Server Management Studio and connect to your SSAS 2016 instance. Click on the **New Query** button and check that the target database is Adventure Works DW 2016. Then execute the following query:

```
SELECT
    { [Internet Sales Amount] } ON 0,
    { [Product].[Color].MEMBERS } ON 1
FROM
    [Adventure Works]
WHERE
    ( { [Date].[Calendar].[Date].&[20131201] :
        [Date].[Calendar].[Date].&[20131224] } )
```

The query returns the value of the `Internet Sales Amount` for each color. Notice that when the range is provided in the slicer, there's no need to define new calculated measure as in the previous recipe; the SSAS engine automatically aggregates each measures using its aggregation function. Because of that, this is the preferred approach for implementing multiselect, although it is rarely found in SSAS frontends.

How to do it...

Follow these steps to calculate parallel periods for multiple dates in a slicer:

1. Define a new calculated member. Name it `Internet Sales PP`. The definition for it should be the sum of the parallel period's values on existing dates of the `Date.Calendar` hierarchy:

```
MEMBER [Internet Sales PP] As
    Sum( EXISTING [Date].[Calendar].[Date].MEMBERS,
        ( ParallelPeriod( [Date].[Calendar].[Calendar Year],
            1,
            [Date Range].Current.Item(0) ),
            [Measures].[Internet Sales Amount] )
        )
    , FORMAT_STRING = 'Currency'
```

2. Add another calculated measure. Name it Internet Sales YoY % and define it as a ratio of the original Internet Sales Amount measure over the Internet Sales PP measure. Be sure to implement a test for division by zero.
3. Add both calculated measures on the columns axis.
4. The final query should look as follows:

```
WITH
MEMBER [Internet Sales PP] As
    Sum( EXISTING [Date].[Calendar].[Date].MEMBERS,
        ( ParallelPeriod( [Date].[Calendar].[Calendar Year],
            1,
            [Date].[Calendar].CurrentMember ),
        [Measures].[Internet Sales Amount] )
    )
, FORMAT_STRING = 'Currency'
MEMBER [Internet Sales YoY %] As
    iif( [Internet Sales PP] = 0, null,
        ( [Measures].[Internet Sales Amount] /
        [Internet Sales PP] ) )
    , FORMAT_STRING = 'Percent'
SELECT
    { [Internet Sales PP],
        [Internet Sales Amount],
        [Internet Sales YoY %] } ON 0,
    { [Product].[Color].MEMBERS } ON 1
FROM
    [Adventure Works]
WHERE
    ( { [Date].[Calendar].[Date].&[20131201] :
        [Date].[Calendar].[Date].&[20131224] } )
```

5. Execute it and observe the results. They should match the results in the previous recipe because the same date range was used in both recipes:

	Internet Sales PP	Internet Sales Amount	Internet Sales YoY %
All Products	\$442,963.98	\$1,622,891.90	366.37%
Black	\$186,775.23	\$457,768.45	245.09%
Blue	(null)	\$232,531.00	(null)
Grey	(null)	(null)	(null)
Multi	(null)	\$8,669.65	(null)
NA	(null)	\$31,495.78	(null)
Red	\$99,960.12	\$20,783.35	20.79%
Silver	\$122,213.76	\$360,631.70	295.08%
Silver/Black	(null)	(null)	(null)
White	(null)	\$413.54	(null)
Yellow	\$34,014.88	\$510,598.43	1501.10%

How it works...

For the purpose of the comparison between the solution in this recipe and that of the previous recipe, *Calculating parallel periods for multiple dates in a set*, we are repeating the calculated members here:

```
-- Sum up the sales over a set of dates from previous year
MEMBER [Internet Sales PP] As
    Sum( { [Date].[Calendar].[Date].&[20131201] :
            [Date].[Calendar].[Date].&[20131224] },
        ( ParallelPeriod( [Date].[Calendar].[Calendar Year],
                           1,
                           [Date].[Calendar].CurrentMember ),
          [Measures].[Internet Sales Amount] )
    )

-- Sum up the sales over a set of dates from previous year
-- when the set of dates for the current year is on the slicer
MEMBER [Internet Sales PP] As
    Sum( EXISTING [Date].[Calendar].[Date].MEMBERS,
        ( ParallelPeriod( [Date].[Calendar].[Calendar Year],
                           1,
                           [Date].[Calendar].CurrentMember ),
          [Measures].[Internet Sales Amount] )
    )
```

Note that the only difference is in the set expression for the `Sum()` function. To detect the multiple members, or a set, in the slicer, we have to use the `EXISTING` keyword. The `EXISTING` keyword forces the specified set, that is, the dates on the `Calendar` hierarchy to be evaluated within the current contexts in the slicer. It serves the purpose of collecting all the members on the leaf level, the `Date` level in this case, that are valid for the current context. Since the slicer is the part of a query that establishes the context, this is a way in which we can detect a currently selected range of members (or any current member on axes in general).

Once we know the dates from the slicer, we can use that range to sum the values of the measure in the parallel period.

Finally, the YoY % ratio is calculated using both measures, `Internet Sales Amount` and `Internet Sales PP`.

There's more...

We can never know exactly what was in the slicer, only *see the shadow of it*. Let's see why.

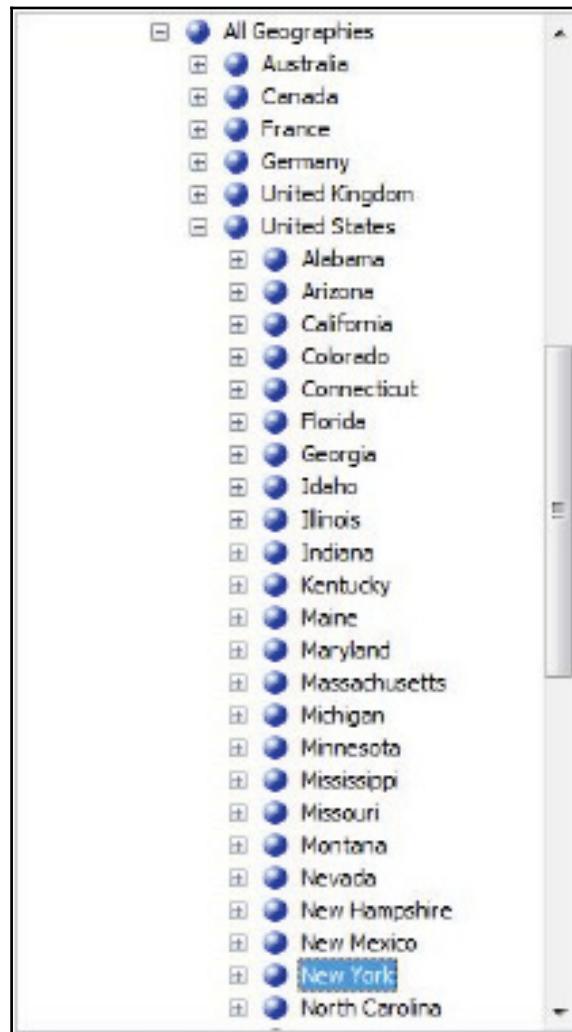

There are two MDX functions that serve the purpose of identifying members in the context. The first is the `CurrentMember` function. The function undoubtedly identifies single members, but it cannot be used for detecting multiple members in context. That's what the `Existing` function does. However, that one is not so precise. In other words, each of them has their purpose, advantages, and disadvantages.

Suppose the slicer contains the city **New York**, a member of the `Geography`.`Geography` user hierarchy. Using the `CurrentMember` function, we can immediately identify the exact member of that hierarchy. We know that the slicer contains **New York** city, not anything above, below, left, or right.

However, if there's also the **United Kingdom** country member, the use of `CurrentMember` is inappropriate; it will result in an error.

In that case, we must use the `Existing` function. That function detects members of a level, not the hierarchy, which makes it less precise. If used on the **Country** level, it will return **United States** and **United Kingdom** although **United States** wasn't in the slicer, but one of its descendants **New York** city. If used on a state-province level, it will return **New York** and all the children of the UK member.

The following screenshot can shed more light on it. It shows the members **New York**, **United Kingdom**, **United States**, and their relative positions; the different levels they are on:

The problem with this is that we never know exactly which members there were. The only way to calculate this correctly is to use the leaf level of a hierarchy because only then can we be sure that our calculation is correct. This can have a serious impact on the performance; leaf level calculations are slow in OLAP.

The other problem with detecting the context is that neither the `Existing` function nor the `CurrentMember` function detects what's in the subselect part of the query. That is not a problem per se, because both the slicer and the subselect have their purpose. The subselect doesn't set the context and so there's no need to know what was in there. However, Excel 2007 and 2010 use subselect in many situations where the slicer should be used instead and that makes many calculations useless because they can't detect the context and adjust to it. Make sure to test calculations in your client tool of choice to see whether it also uses unnecessary subselects.

Here's a blog post by Mosha Pasumansky that shows how to use dynamically named sets to detect the contents of subselect: <http://tinyurl.com/MoshaSubselect>.

The difference between them comes from the fact that the original period can be present in various places within an MDX query and that there are one or more dates the parallel period should be calculated for. Based on that, an appropriate recipe should be applied. Therefore, in order to understand and memorize the differences between them, it is suggested that you read all of the recipes dealing with parallel periods.

Concise Reporting

In this chapter, we will cover the following recipes:

- Isolating the best N members in a set
- Isolating the worst N members in a set
- Identifying the best/worst members for each member of another hierarchy
- Displaying a few important members, with the others as a single row, and the total at the end
- Combining two hierarchies into one
- Finding the name of a child with the best/worst value
- Highlighting siblings with the best/worst values
- Implementing bubble-up exceptions

Introduction

A crucial part of report design is determining what the appropriate level of information will be presented to the business users. The appropriate level of information must be carefully matched to any business requirements, with maximized benefit to the business and minimum performance impact.

Every analytical reporting project has different requirements. In this chapter, we are going to focus on techniques that you can employ in your project to make analytical reports more compact and more concise, and therefore more efficient.

Recipes in this chapter can be implemented in pivot tables, the analytical component found in any SSAS frontend in one form or another. **SQL Server Reporting Services (SSRS)** report developers will also find these recipes very useful since they can implement these methods directly in an SSRS report.

The problem with pivot table-style reports is that they tend to grow very large very quickly. Including several hierarchies on rows, and some on columns, will result in a very large table.

The analysis of a large table can be very difficult. Even worse, when presenting a large amount of data in a chart, it might not be very readable when the number of items crosses a certain threshold.

The solution is to make reports compact; to focus on what is important to business users in your project. This chapter offers several techniques for reducing the amount of data reported without losing any crucial information.

We will start with several recipes dealing with the isolation of important members, whether they are from only one hierarchy or from multiple.

We will also present a unique way of presenting data in one single report that includes three sections: the top N members, the other members as a single row, and the total at the end.

This chapter also includes a trick for combining members from two different hierarchies into one column.

In the last three recipes, we will cover techniques for presenting data at a higher granular level, whilst extracting additional information at the lower granular level and color-coding the foreground and/or background of certain important cells.

Isolating the best N members in a set

Hierarchies can contain a lot of members. In this recipe, we are going to show you how to extract only the significant members: ones with the highest value for a certain measure.

This requirement is often necessary because not only does it allow end users to focus their efforts on a smaller set of members, but it also makes the queries much faster.

We will base our example on the `TopCount()` function, a function that returns the exact number of members as specified. In addition to that function, MDX has two more similar functions, namely `TopPercent()` and `TopSum()`. Contrary to the `TopCount()` function, these functions return an unknown number of members. In other words, they are designed to return a set of members based on their contribution, in a percentage or in an absolute value, respectively.

Further similarities and differences between `TopCount()`, `TopSum()`, and `TopPercent()` functions will be covered in later sections of this recipe.

Getting ready

Start SQL Server Management Studio and connect to your SSAS 2016 instance. Click on the **New Query** button and check that the target database is Adventure Works DW 2016.

In this example, we are going to use the Reseller dimension. Here is the query we will start from:

```
WITH
SET [Ordered Resellers] AS
    Order( [Reseller].[Reseller].[Reseller].MEMBERS,
           [Measures].[Reseller Sales Amount],
           BDESC )
SELECT
    { [Measures].[Reseller Sales Amount] } ON 0,
    { [Ordered Resellers] } ON 1
FROM
    [Adventure Works]
```

Once executed, this query returns reseller sales values for each individual reseller, where the resellers themselves are sorted in descending order of Reseller Sales Amount. Our task is to extract only five of them, those with the highest sales amount:

	Reseller Sales Amount
Brakes and Gears	\$877,107.19
Excellent Riding Supplies	\$853,849.18
Vigorous Exercise Company	\$841,908.77
Totes & Baskets Company	\$816,755.58
Retail Mall	\$799,277.90
Comer Bicycle Supply	\$787,773.04
Outdoor Equipment Store	\$746,317.53
Thorough Parts and Repair Services	\$740,985.83
Health Spa, Limited	\$730,798.71
Fitness Toy Store	\$727,272.65
Latest Sports Equipment	\$724,299.64
First Bike Store	\$711,864.76
Great Bikes	\$700,803.79
Farthermost Bike Shop	\$693,502.49
Field Trip Store	\$671,618.03

How to do it...

We are going to use the `TopCount()` function to return the top five resellers with the highest sales amount.

Follow these steps to create a named set with the `TopCount()` function:

1. Create a new calculated set and name it `Top 5 Resellers`.
2. Define it using the `TopCount()` function, where the first argument is the set of reseller members, the second is the number 5, and the third is the measure `Reseller Sales Amount`.
3. Remove the `Ordered Resellers` set from the query and put the `Top 5 Resellers` on the rows instead.
4. The query should look as follows. Execute it:

```
WITH
SET [Top 5 Resellers] AS
    TopCount( [Reseller].[Reseller].[Reseller].MEMBERS,
              5,
              [Measures].[Reseller Sales Amount] )
SELECT
    { [Measures].[Reseller Sales Amount] } ON 0,
    { [Top 5 Resellers] } ON 1
FROM
    [Adventure Works]
```

5. Only the five rows with the highest values should remain, as displayed in the following screenshot:

	Reseller Sales Amount
Brakes and Gears	\$877,107.19
Excellent Riding Supplies	\$853,849.18
Vigorous Exercise Comp...	\$841,908.77
Totes & Baskets Company	\$816,755.58
Retail Mall	\$799,277.90

6. Compare the rows returned with the ones from the initial query in this recipe. They should be the same, in the exact same order, and with the exact same values, but with only the top five resellers returned.

How it works...

The `TopCount()` function takes three arguments. The first one is a set of members that is to be limited. The second argument is the number of members to be returned. The third argument is an expression to be used for determining the order of members.

In this example, we asked for the five resellers with the highest value of the measure `Reseller Sales Amount`. Using the `TopCount()` function, we got exactly that.

It's worth mentioning that the `TopCount()` function always sorts the returned items in descending order of the measure.

There's more...

The most important argument of the `TopCount()` function is the third argument. That is, what determines how the members will be sorted internally so that only the top N of them remain afterwards. As mentioned earlier, the argument is an expression. This expression can be a single measure, an expression including several measures, a single tuple, multiple tuples, or anything that evaluates to a scalar value.

The top N members is evaluated in All Periods, not in the context of the opposite query axis

As seen in the previous example, returning the top N members is quite easy with the `TopCount()` function. However, in MDX, it is also relatively easy to make a mistake and return members we do not intend to.

Here is one scenario in which that can happen.

We position a member of another hierarchy (for example, the year 2013 from the calendar year hierarchy) on the opposite query axis (on columns), expecting the `TopCount()` function to include that in its third argument. In the following query, you might mistakenly expect that the `TopCount()` function will return the top N members in the single year 2013. It will not:

```
WITH
SET [Top 5 Resellers] AS
    TopCount( [Reseller].[Reseller].[Reseller].MEMBERS,
              5,
              [Measures].[Reseller Sales Amount] )
SELECT
```

```
{ [Measures].[Reseller Sales Amount] } *
{ [Date].[Calendar Year].&[2013] } ON 0,
{ [Top 5 Resellers] } ON 1
FROM
[Adventure Works]
```

The result is shown in the following screenshot. The question is – what does it represent?

Reseller Sales Amount	
CY 2013	
Brakes and Gears	\$397,237.24
Excellent Riding Supplies	\$276,729.43
Vigorous Exercise Comp...	\$255,750.52
Totes & Baskets Company	\$289,777.50
Retail Mall	\$159,235.27

The result contains the same top five resellers which are evaluated in the context of all years, with their sales amount in the single year 2013 displayed on the columns. In other words, we got the best N members in all years but then displayed their sales amount for a single year, 2013.

The data itself is correct, but the result is not what we intended. Notice that the sales amount for the year 2013 in the previous screenshot is not ordered in descending order. This is a clue that we have made a mistake.

The query and its subsequent result should also confirm that we have made a mistake in the previous query. In the following query, we have placed the All Periods in the slicer and queried the same top five resellers, which are evaluated in the context of all years. We then displayed their sales amount for each year. Notice that only the first column All Periods is sorted in descending order. Also, notice that the column CY 2013 shows the same sales amount as the previous screenshot:

```
WITH
SET [Top 5 Resellers] AS
TopCount( [Reseller].[Reseller].[Reseller].MEMBERS,
5,
[Measures].[Reseller Sales Amount] )
SELECT
NON EMPTY
{ [Measures].[Reseller Sales Amount] } *
{ [Date].[Calendar Year].MEMBERS } ON 0,
```

```
{ [Top 5 Resellers] } ON 1  
FROM  
[Adventure Works]  
WHERE  
( [Date].[Calendar].[All Periods] )
```

	Reseller Sales Amount				
	All Periods	CY 2010	CY 2011	CY 2012	CY 2013
Brakes and Gears	\$877,107.19	(null)	\$185,995.56	\$293,874.39	\$397,237.24
Excellent Riding Supplies	\$853,849.18	(null)	\$180,664.82	\$396,454.93	\$276,729.43
Vigorous Exercise Company	\$841,908.77	(null)	\$300,525.66	\$285,632.59	\$255,750.52
Totes & Baskets Company	\$816,755.58	(null)	\$167,106.04	\$359,872.04	\$289,777.50
Retail Mall	\$799,277.90	\$35,944.16	\$303,068.51	\$301,029.95	\$159,235.27

Is it possible to see how we have made such a mistake? Yes, although not necessarily every time.

In most cases, it is a clue that something went wrong with the calculation when the results are not shown in descending order or when the number of rows is fewer than specified.

So, what is the reason for this kind of behavior?

The top N members will be evaluated in the context of the slicer

Axes are independent. Only the members in the slicer are implicitly included in the third argument of the TopCount() function (which is a mechanism known as **Deep Autoexists**: <http://tinyurl.com/AutoExists>). To be precise, any outer MDX construct also sets the context, but here we didn't have such a case, so we can focus on the slicer and axes relation only. To conclude, only when the year 2013 is found in the slicer will the third argument then be expanded into a tuple, and the result will be evaluated as the top N members in the year 2013.

Execute the following query and compare its result with the query that had the year 2013 on the opposite axis (visible in the previous screenshot):

```
WITH  
SET [Top 5 Resellers] AS  
    TopCount( [Reseller].[Reseller].[Reseller].MEMBERS,  
              5,  
              [Measures].[Reseller Sales Amount] )  
SELECT  
    { [Measures].[Reseller Sales Amount] } ON 0,
```

```
{ [Top 5 Resellers] } ON 1  
FROM  
[Adventure Works]  
WHERE  
( [Date].[Calendar Year].&[2013] )
```

Notice that the members on the rows have changed. These resellers are the top five resellers in the single year 2013. Also, notice that their values are shown in descending order:

	Reseller Sales Amount
Roadway Bicycle Supply	\$436,921.66
Field Trip Store	\$427,305.59
Brakes and Gears	\$397,237.24
Perfect Toys	\$391,040.59
Thorough Parts and Repair Services	\$386,958.19

Using a tuple in the third argument of the TopCount() function to overwrite the member on the slicer

Now, let us take a look at another type of mistake, that is, when we want to override the context on the slicer but forget to do so in the third argument of the TopCount () function. For example, when the year 2013 is in the slicer, we want to get the top N members from the previous year, 2012.

Why would we want to do such a thing? Because we want to analyze how last year's best resellers are doing this year.

If that is the case, we must provide a tuple as the third argument. The idea of the tuple is to overwrite the context set by the slicer with the member from the same hierarchy used inside the tuple. Remember, it should be the same hierarchy or it will not work.

Following the previous example, where the year 2013 is on the slicer, we must change the third argument of the TopCount () function to include a tuple:

```
( [Measures].[Reseller Sales Amount],  
[Date].[Calendar Year].&[2012] )
```

The year 2012 is in the tuple to overwrite the year 2013 in the slicer.

Here is the final query:

```
WITH
SET [Top 5 Resellers in 2012] AS
    TopCount( [Reseller].[Reseller].[Reseller].MEMBERS,
               5,
               ( [Measures].[Reseller Sales Amount],
                 [Date].[Calendar Year].&[2012] ) )
SELECT
    { [Measures].[Reseller Sales Amount] } ON 0,
    { [Top 5 Resellers in 2012] } ON 1
FROM
    [Adventure Works]
WHERE
    ( [Date].[Calendar Year].&[2013] )
```

Develop a habit of naming the top N sets that use tuples appropriately (see earlier). Remember that although the slicer or the outer MDX construct determines the context for the values to be displayed and for the functions to be evaluated, we can always override that to adjust the set we're after.

Testing the correctness of the result

The equivalent syntax of the `TopCount()` function is this:

```
Head( Order( [Reseller].[Reseller].[Reseller].MEMBERS,
              [Measures].[Reseller Sales Amount],
              BDESC ), 5 )
```

Although this construct can be useful for testing the correctness of the result, `TopCount()` is the preferred way of implementing the requirement of isolating the best N members. This is because the `Order()` function is a relatively slow MDX function because it materializes the set, and the query optimizer may not be successful in optimizing the query by recognizing the `Head-Order` construct as a `TopCount()` function.

Multidimensional sets

The first argument in the `TopCount()` function takes a set expression. In our examples, we only used a one-dimensional set that has only one hierarchy reseller. In this case, the second argument N determines the number of members from the one-dimensional set to be returned.

In the case of multidimensional sets that are made of more than one hierarchy, the second argument N determines the number of tuples to be returned. The returned tuples are also sorted in descending order of the numeric expression.

TopPercent() and TopSum() functions

As we said in the introduction, `TopPercent()` and `TopSum()` are two functions similar to the `TopCount()` function. The first one returns an unknown number of members. In `TopPercent()`, the second argument determines the percentage of them to be returned, starting from the ones with the highest values, and ending when the total value of the members included compared to the total value of all members reaches the percentage specified in that function. The second one works on the same principle, except that it is the absolute value and not the percentage that is specified and compared. For example, `TopPercent()` with 80 means that we want the top members who form 80 percent of the total result. `TopSum()` with 1,000,000 means that we want members whose total forms that value, looking from the member with the highest value and adding all of them below until that value is reached.

The same principles, ideas, and warnings apply to all top-something functions.

- Refer to the *Isolating the worst N members in a set* and *Identifying the best/worst members for each member of another hierarchy* recipes in this chapter

Isolating the worst N members in a set

In the previous recipe, we showed you how to identify members with the highest result. In this recipe, we will do the opposite and return those with the lowest result.

Getting ready

Start SQL Server Management Studio and connect to your SSAS 2016 instance. Click on the **New Query** button and check that the target database is Adventure Works DW 2016.

In this example, we are going to use the Reseller dimension. Here is the query we will start from:

```
WITH
SET [Ordered Resellers] AS
    Order( [Reseller].[Reseller].[Reseller].MEMBERS,
           [Measures].[Reseller Sales Amount],
           BASC )
SELECT
    { [Measures].[Reseller Sales Amount] } ON 0,
    { [Ordered Resellers] } ON 1
FROM
    [Adventure Works]
```

Once executed, that query returns reseller sales values for every individual reseller, where the resellers themselves are sorted in ascending order of the sales amount. Our task is to extract only the five with the worst sales amount.

How to do it...

We are going to use the `BottomCount()` function to return the bottom five resellers with the worst sales amount.

Follow these steps to create a named set with the `BottomCount()` function:

1. Create a new calculated set and name it `Bottom 5 Resellers`.
2. Define it using the `BottomCount()` function, where the first argument is the set of reseller members, the second is the number 5, and the third is the measure `Reseller Sales Amount`.

3. Apply the NonEmpty() function over the set specified as the first argument using the same measure as in the third argument of the BottomCount() function:

```
SET [Bottom 5 Resellers] AS
BottomCount(
    NonEmpty( [Reseller].[Reseller].[Reseller].MEMBERS,
        { [Measures].[Reseller Sales Amount] } ),
    5,
    [Measures].[Reseller Sales Amount]
)
```

4. Remove the Ordered Resellers set from the query and put the Bottom 5 Resellers on rows instead.
5. The query should look as follows. Execute it:

```
WITH
SET [Bottom 5 Resellers] AS
BottomCount(
    NonEmpty( [Reseller].[Reseller].[Reseller].MEMBERS,
        [Measures].[Reseller Sales Amount] ),
    5,
    [Measures].[Reseller Sales Amount]
)
SELECT
    { [Measures].[Reseller Sales Amount] } ON 0,
    { [Bottom 5 Resellers] } ON 1
FROM
    [Adventure Works]
```

6. Only the five rows with the lowest values should remain, as displayed in the following screenshot:

	Reseller Sales Amount
Mobile Outlet	\$1.37
Parts Shop	\$24.29
Eleventh Bike Store	\$57.68
Large Bike Shop	\$58.07
Essential Bike Works	\$59.33

7. Compare the rows returned with the ones from the initial query in this recipe. If we ignore the empty rows from the initial rows, they should be the same, in the exact same order, and with the exact same values; only the new query returned only the lowest five resellers.

How it works...

The `BottomCount()` function takes three arguments. The first one is a set of members that is going to be limited. The second argument is the number of members to be returned. The third argument is the expression for determining the order of members.

In this example, we asked for the five resellers with the lowest value of the measure `Reseller Sales Amount`. Using the `BottomCount()` function alone, without applying the inner `NonEmpty()` function on the following tuple, we would get five rows with empty values:

```
NonEmpty( [Reseller].[Reseller].[Reseller].MEMBERS,  
          [Measures].[Reseller Sales Amount] )
```

We can think of values, once sorted, as being separated into four groups: positive values, zero values, null values, and negative values. Those groups appear in that particular order once sorted in descending order, and in the reverse order once sorted in ascending order.

In the `TopCount()` function covered in the previous recipe, we didn't experience the effect of null values because the results were all positive. In the `BottomCount()` function, this is something that needs to be taken care of, particularly if there are no negative values. The reason we want to get rid of null values is because, from a business perspective, those values represent no activity. What we are interested in is identifying members with activity.

That's the reason we applied the `NonEmpty()` function in the third step of this recipe. That action removed all members with a null value in that particular context, leaving only members with activity to the outer `BottomCount()` function.

It's worth mentioning that the `BottomCount()` function always sorts the rows in ascending order.

There's more...

The `BottomPercent()` and `BottomSum()` are two functions similar to the `BottomCount()` function. They are the opposite functions of the `TopPercent()` and `TopSum()` functions explained in the last section of the previous recipe. The same principles, ideas, and warnings also apply here.

Identifying the best/worst members for each member of another hierarchy

Sales territory country and reseller are two different hierarchies in Adventure Works DW. To analyze sales, we might choose not to look at every reseller in every country. Instead, we often only need to look for the top or bottom N resellers per country.

In this case, we can view the country as the outer hierarchy, and the reseller as the inner hierarchy. Quite often, we need to analyze the combination of hierarchies in a way that the top or bottom N members of the inner hierarchy are displayed for each member of the outer hierarchy.

Displaying only the top or bottom N members of the inner hierarchy for each member of the outer hierarchy is sort of a report reduction, where we preserve the important combinations of members and leave out the rest of the cross join.

This recipe shows you how to create a `TopCount()` calculation to retrieve the top N resellers in each sales territory.

Getting ready

Start SQL Server Management Studio and connect to your SSAS 2016 instance. Click on the **New Query** button and check that the target database is Adventure Works DW 2016.

In this example, we are going to use the Sales Territory dimension and the Reseller dimension. Here is the query we will start from:

```
WITH
SET [Ordered Resellers] AS
    Order( [Reseller].[Reseller].[Reseller].MEMBERS,
           [Measures].[Reseller Sales Amount] ,
           BDESC )
SELECT
    { [Measures].[Reseller Sales Amount] } ON 0,
NON EMPTY
    { [Sales Territory].[Sales Territory Country].MEMBERS *
      [Ordered Resellers] } ON 1
FROM
    [Adventure Works]
```

Once executed, the earlier query returns reseller sales values for every individual reseller and country, where the resellers themselves are sorted in descending order of the sales amount for each country:

		Reseller Sales Amount
All Sales Territories	Hometown Riding Supplies	\$144.00
All Sales Territories	Retail Cycle Shop	\$91.18
All Sales Territories	Extras Sporting Goods	\$67.54
All Sales Territories	Essential Bike Works	\$59.33
All Sales Territories	Large Bike Shop	\$58.07
All Sales Territories	Eleventh Bike Store	\$57.68
All Sales Territories	Parts Shop	\$24.29
All Sales Territories	Mobile Outlet	\$1.37
Australia	Nationwide Supply	\$221,169.78
Australia	Rich Department Store	\$148,996.51
Australia	Gears and Parts Company	\$145,407.74
Australia	Budget Toy Store	\$145,380.13
Australia	Helmets and Cycles	\$116,300.95
Australia	Cycle Parts and Accessories	\$115,085.64
Australia	Helpful Sales and Repair Service	\$106,761.09
Australia	Popular Bike Lines	\$105,590.13

Our task is to extract the five resellers with the best sales for each country. We would expect a different top five resellers in each country.

How to do it...

We are going to use the `Generate()` function together with the `TopCount()` function to return the top five resellers in each country.

Follow these steps to create a calculated set of the top five resellers per country:

1. Define a new calculated set; name it `Top 5 Resellers per Country`.
2. Use the `Generate()` function as a way of performing the iteration.
3. Provide the set of countries found on rows as the first argument of that `Generate()` function.
4. Provide the second argument of that function in the form of a cross join of the current member of countries hierarchy and the `TopCount()` function applied to the set of resellers.
5. Put that new calculated set on the rows, instead of having everything there.
6. Verify that the query looks like this and then execute it:

```
WITH
SET [Top 5 Resellers per Country] AS
Generate(
    [Sales Territory].[Sales Territory Country].MEMBERS,
    { [Sales Territory].[Sales Territory Country]
        .CurrentMember } *
    TopCount( [Reseller].[Reseller].[Reseller].MEMBERS,
        5,
        [Measures].[Reseller Sales Amount] )
)
SELECT
    { [Measures].[Reseller Sales Amount] } ON 0,
NON EMPTY
    { [Top 5 Resellers per Country] } ON 1
FROM
    [Adventure Works]
```

7. The result is shown in the following screenshot. It returned different resellers for each country; they are the top five resellers relative to each country:

		Reseller Sales Amount
All Sales Territories	Brakes and Gears	\$877,107.19
All Sales Territories	Excellent Riding Supplies	\$853,849.18
All Sales Territories	Vigorous Exercise Company	\$841,908.77
All Sales Territories	Totes & Baskets Company	\$816,755.58
All Sales Territories	Retail Mall	\$799,277.90
Australia	Nationwide Supply	\$221,169.78
Australia	Rich Department Store	\$148,996.51
Australia	Gears and Parts Company	\$145,407.74
Australia	Budget Toy Store	\$145,380.13
Australia	Helmets and Cycles	\$116,300.95
Canada	Vigorous Exercise Company	\$841,908.77
Canada	Retail Mall	\$799,277.90
Canada	Corner Bicycle Supply	\$787,773.04
Canada	Health Spa, Limited	\$730,798.71
Canada	Top Sports Supply	\$602,559.89
France	Metropolitan Equipment	\$643,745.90
France	Registered Cycle Store	\$580,222.33

Notice that the results are ordered as descending inside each country.

How it works...

The `Generate()` function is a loop. Using that function, we can iterate over a set of members and create another set of members, as explained in the *Iterating on a set to create a new one* recipe in Chapter 2, *Working with Sets*.

In this recipe, we used it to iterate over a set of countries and to create another set, a set that is formed as a combination of the current country in the loop and the top five resellers in the context of that country.

Notice that we simply used the measure [Reseller Sales Amount] as the third argument for the TopCount() function. The loop sets the context; that is why we do not need to expand the third argument of the TopCount() function into a tuple. The following tuple would be redundant:

```
( [Sales Territory].[Sales Territory Country].CurrentMember,  
[Measures].[Reseller Sales Amount] )
```

That current member is already implicitly there and set by the outer loop, the Generate() function.

To display each country and its top five resellers on rows, we had to build a multidimensional set in advance using the cross-production of two sets, as shown:

```
{ [Sales Territory].[Sales Territory Country].CurrentMember } *  
TopCount( [Reseller].[Reseller].[Reseller].MEMBERS,  
5,  
[Measures].[Reseller Sales Amount] )
```

Because of the outer Generate() function, this multidimensional set is obtained in iteration, where the top five resellers are identified for each country.

There's more...

Was it really necessary to define such a complex syntax? Couldn't we have done something simpler instead? Let's see.

One idea would be to define Top 5 Resellers as we did in the first recipe of this chapter and use it on rows:

```
WITH  
SET [Top 5 Resellers] AS  
TopCount( [Reseller].[Reseller].[Reseller].MEMBERS,  
5,  
[Measures].[Reseller Sales Amount] )  
SELECT  
{ [Measures].[Reseller Sales Amount] } ON 0,  
NON EMPTY  
{ [Sales Territory].[Sales Territory Country]  
.[Sales Territory Country].MEMBERS *  
[Top 5 Resellers] } ON 1  
FROM  
[Adventure Works]
```

When this query is run, it returns the total of five rows, as seen in the following screenshot:

		Reseller Sales Amount
Canada	Vigorous Exercise Company	\$841,908.77
Canada	Retail Mall	\$799,277.90
United States	Brakes and Gears	\$877,107.19
United States	Excellent Riding Supplies	\$853,849.18
United States	Totes & Baskets Company	\$816,755.58

The results are not sorted in any particular order, which is the first indicator that something is wrong. The number of returned items is fewer than expected. That is the second indicator.

To see what went wrong, we need to comment out the `NON EMPTY` keyword and execute the same query again. This time, we can see more clearly what is going on:

		Reseller Sales Amount
Australia	Brakes and Gears	(null)
Australia	Excellent Riding Supplies	(null)
Australia	Vigorous Exercise Company	(null)
Australia	Totes & Baskets Company	(null)
Australia	Retail Mall	(null)
Canada	Brakes and Gears	(null)
Canada	Excellent Riding Supplies	(null)
Canada	Vigorous Exercise Company	\$841,908.77
Canada	Totes & Baskets Company	(null)
Canada	Retail Mall	\$799,277.90
France	Brakes and Gears	(null)
France	Excellent Riding Supplies	(null)
France	Vigorous Exercise Company	(null)
France	Totes & Baskets Company	(null)

Resellers repeat in each country. The group of resellers marked in the preceding screenshot can be found preceding and following that country.

It wouldn't help to expand the third argument of the `TopCount()` function into a tuple either. The following tuple would not help:

```
( [Sales Territory].[Sales Territory Country].CurrentMember,  
[Measures].[Reseller Sales Amount] )
```

The reason why this doesn't work is because calculated sets are evaluated once – after the slicer and before the iteration on cells. Therefore, the `TopCount()` function is evaluated in the context of the default country, the root member, and not within the context of each country. That is why the resellers repeat in each country.

While calculated sets are evaluated only once before each cell is evaluated, calculated members, on the other hand, are evaluated for each cell. We cannot use a calculated member in this case, because we need a set of five members. The only thing that's left is to use the outer `Generate()` function to push each country into the set. By having everything in advance before the iteration on the cells begins, we can prepare the required multidimensional set of countries and their best resellers.

Support for the relative context and multidimensional sets in SSAS frontends

Frontends perform cross join operations while allowing end users to filter and isolate members of hierarchies to limit the size of the report. Some frontends even allow functions, such as the `TopCount()` function, to be applied visually, without editing the actual MDX. The thing they rarely do is to allow the `TopCount()` function to be applied relatively to another hierarchy.

As we have seen, without the relative component, the top N members are calculated in the context of another hierarchy's root member, not individual members in the query. The only solution is to define a multidimensional set using the `Generate()` function. With this comes another problem – multidimensional sets (sets that contain members from more than one attribute) are not supported in many frontends. Test the limitations of your tool to know whether you can use it as a frontend feature, implement it in a cube as a multidimensional set, or write an MDX query.

- Refer to the *Isolating the best N members in a set* and *Isolating the worst N members in a set* recipes in this chapter

Displaying a few important members, with the others as a single row, and the total at the end

There are times when isolating the best or worst members is not enough. In addition to the few important members, business users often want to see the total of all the other not-so-important members, as well as a single row representing the total of all the members.

An example of this type of reporting requirement is shown in the following table:

	Reseller Sales Amount
Top 1st Reseller	\$877,107.19
Top 2nd Reseller	\$853,849.18
Top 3rd Reseller	\$841,908.77
Top 4th Reseller	\$816,755.58
Top 5th Reseller	\$799,277.90
Other Resellers	\$76,261,698.37
All Resellers	\$80,450,596.98

In the first recipe in this chapter, *Isolating the best N members in a set*, we learned how to isolate the best members using the `TopCount()` function. The challenge in this recipe is to get only one row for the total of all **Other Resellers**, and only one row for the total of **All Resellers**. We will also need to make sure that **Top N Resellers**, **Other Resellers** and **All Resellers** are all combined into one column. This recipe shows you how to fulfill this type of reporting requirement.

Getting ready

Start SQL Server Management Studio and connect to your SSAS 2016 instance. Click on the **New Query** button and check that the target database is Adventure Works DW 2016.

In this example, we're going to use the `Reseller` dimension. Here's the query we'll start from:

```
WITH
SET [Ordered Resellers] AS
    Order( [Reseller].[Reseller].[Reseller].MEMBERS,
           [Measures].[Reseller Sales Amount],
           BDESC )
SELECT
    { [Measures].[Reseller Sales Amount] } ON 0,
    { [Ordered Resellers] } ON 1
FROM
    [Adventure Works]
```

This query returns values of the `Reseller Sales Amount` measure for every single reseller. Notice that we purposely sorted the resellers in descending order of the sales amount:

	Reseller Sales Amount
Brakes and Gears	\$877,107.19
Excellent Riding Supplies	\$853,849.18
Vigorous Exercise Company	\$841,908.77
Totes & Baskets Company	\$816,755.58
Retail Mall	\$799,277.90
Comer Bicycle Supply	\$787,773.04
Outdoor Equipment Store	\$746,317.53
Thorough Parts and Repair Services	\$740,985.83
Health Spa, Limited	\$730,798.71

Our goal is to keep only the top five resellers highlighted in the preceding screenshot, with two additional rows. One of the additional rows is for other resellers, and the other one is for all resellers.

How to do it...

Follow these steps to return the Top 5 Resellers, followed by one row for Other Resellers and one row for All Resellers, all in one query:

1. Create a new calculated set and name it Top 5 Resellers.
2. Define it using the TopCount() function, where the first argument is the set of reseller members, the second is the number 5, and the third is the measure Reseller Sales Amount. In short, the definition should be this:

```
SET [Top 5 Resellers] AS  
    TopCount( [Reseller].[Reseller].[Reseller].MEMBERS,  
              5,  
              [Measures].[Reseller Sales Amount] )
```

3. Remove the Ordered Resellers set from the query and put the Top 5 Resellers on the rows instead.
4. Execute the query. Only the five rows with the highest values should remain.
5. Next, create a new calculated member and name it Other Resellers. Use the following definition:

```
MEMBER [Reseller].[Reseller].[All].[Other Resellers] AS  
    Aggregate( - [Top 5 Resellers] )
```

6. Include that member on the rows, next to the set.
7. Finally, include the root member of the Reseller.Reseller hierarchy in a more generic way by adding its [All] level as the last set on the rows and run the query:

```
WITH  
SET [Top 5 Resellers] AS  
    TopCount( [Reseller].[Reseller].[Reseller].MEMBERS,  
              5,  
              [Measures].[Reseller Sales Amount] )  
MEMBER [Reseller].[Reseller].[All].[Other Resellers] AS  
    Aggregate( - [Top 5 Resellers] )  
SELECT  
    { [Measures].[Reseller Sales Amount] } ON 0,  
    { [Top 5 Resellers],  
      [Reseller].[Reseller].[All].[Other Resellers],  
      [Reseller].[Reseller].[All] } ON 1  
FROM  
    [Adventure Works]
```

8. The result will display seven rows: the top five resellers, the other resellers in a single row, and the total in the form of the root member:

	Reseller Sales Amount
Brakes and Gears	\$877,107.19
Excellent Riding Supplies	\$853,849.18
Vigorous Exercise Company	\$841,908.77
Totes & Baskets Company	\$816,755.58
Retail Mall	\$799,277.90
Other Resellers	\$76,261,698.37
All Resellers	\$80,450,596.98

How it works...

The first part of the solution is to isolate the top N members. This is done relatively easily using the `TopCount()` function. The more detailed explanation of this part is covered in the first recipe of this chapter.

The second part is what is special about this type of report. All other members are obtained using the negation of a set, which is written as a minus followed by that set. This is explained in the *Implementing NOT IN set logic* recipe in Chapter 2, *Working with Sets*.

Next, that negative set expression is wrapped inside the `Aggregate()` function, which compacts that set into a single calculated member. That calculated member is the row that follows the top N members in the result.

Finally, the root member of that hierarchy comes as the last row, which acts as a total of rows. Here, it's worth noting that we didn't use the root member's name `[All Resellers]`; we've used its level name `[All]`. The reason for this is explained in the next section.

There's more...

The beauty of this solution is that the initial set, in this case `Top 5 Resellers`, can be any set. For example, the initial set can be the bottom N members, members that are a result of a `Filter()` function, existing members for the current context – pretty much anything. It does not matter how many members there are in the initial set. All the rest will be aggregated in a single row.

If we go one step further and use a report parameter in the place of the `Reseller.Reseller` hierarchy, the query will work for any hierarchy without the need to change anything.

Another thing that makes this query generic is the way we referred to the root member. We didn't use its unique name (which would be different for different hierarchies) `[All Resellers]`. We used its level name `[All]` instead. `[All]` is a generic level name for every attribute hierarchy.

Notice that we created a calculated member for `Other Resellers`, but not for `All Resellers`. All resellers became the header for the last total row. To make this report a bit more user-friendly, we could change the header to `Total`. We will need to create a calculated member for the root member to change the header for the last total row.

The root member, found in the `[All]` level, is usually named as `All` or `All Something`. In our example, it's `All Resellers`. The following calculated member is named `Total`, which is an alias for the `All Resellers` member:

```
MEMBER [Reseller].[Reseller].[All].[Total] AS  
      [Reseller].[Reseller].[All]
```

If we replace `[Reseller].[Reseller].[All]` with this calculated member on rows, the header for the last total row will be changed to `Total`.

Making the query even more generic

The query in this recipe referred to the `Reseller.Reseller` hierarchy. By replacing any reference to that hierarchy with a report parameter, we can make the query more generic. Of course, that also means we should remove the word `Reseller` from `[Top 5 Resellers]` and `[Other Resellers]`.

We could then parameterize the whole query and insert any hierarchy and its level in it, in their corresponding places. While `Reseller.Reseller` is a unique name for a hierarchy, `Reseller.Reseller.Reseller` is the unique name of a level on that hierarchy. Therefore, any reference to the `Reseller.Reseller` hierarchy could be replaced by a parameter, say, `@HierarchyUniqueName`, and any reference to the `Reseller.Reseller.Reseller` level could be replaced by a parameter, say, `@LevelUniqueName`. Once such a query is built as a template, it can be executed as a regular query by passing dynamic parameters to it.

To provide meaningful results for the chosen hierarchy and its level, we can also parameterize the measure.

Combining two hierarchies into one

The result of a query contains as many metadata columns as there are hierarchies on rows. For example, if we put two hierarchies on rows, the color and size of products, there will be two columns of metadata information, one for each hierarchy. In the first column, we will have all colors and in the second column we will have all sizes. Depending on the relationship between those hierarchies, we will get either a full cross join for unrelated hierarchies (different dimensions) or a reduced set of valid combinations (in case of the same dimension). In any case, there will be two columns.

Reports grow large very quickly. Once you put several hierarchies either on rows or on columns, suddenly you don't see data; all you see is metadata. That is, column and row headers. Sure, you can modify the layout of the pivot table, but still the report is not clear. Therefore, it's not uncommon that business users want to reduce a report's size, especially the width, by combining multiple hierarchies into a single column.

The question is – can this be achieved in MDX? I know you've already guessed it: yes, it can. This recipe shows the trick of how to make a report compact by combining two hierarchies in a single metadata column.

The example we will present in this recipe is to display the **Month of Year** on rows, the **Reseller Sales Amount** on columns, and then append only the **Last Week** sales amount to the end of the report.

Getting ready

Start SQL Server Management Studio and connect to your SSAS 2016 instance. Click on the **New Query** button and check that the target database is Adventure Works DW 2016.

In this example, we're going to use the `Date` dimension and its two incompatible hierarchies; months and weeks. We are going to show you how to create a report that contains all months up to the *current* month and then how to add the last week of sales in the same column.

Here's the query we'll start from:

```
SELECT
    { [Measures].[Reseller Sales Amount] } ON 0,
    NON EMPTY
    { [Date].[Calendar].[Month].MEMBERS } ON 1
FROM
    [Adventure Works]
WHERE
    ( [Date].[Calendar Year].&[2013] )
```

Once executed, the query returns the values of the `Reseller Sales Amount` measure for 11 months of the year 2013:

	Reseller Sales Amount
January 2013	\$4,212,971.51
February 2013	\$4,047,574.04
March 2013	\$2,282,115.88
April 2013	\$3,483,161.40
May 2013	\$3,510,948.73
June 2013	\$1,662,547.32
July 2013	\$2,699,300.79
August 2013	\$2,738,653.62
September 2013	\$2,206,725.22
October 2013	\$3,314,600.78
November 2013	\$3,416,234.85

The data in the Adventure Works cube ends with **November 2013**, which is the reason why we picked this example to simulate the *current* month in a year situation.

Our goal is to append one more row to the result: the last week's sales amount.

How to do it...

Follow these steps to create a calculated member Last week and place it in the Month of Year hierarchy, so Last week can be displayed in the same column as Month of Year:

1. Replace the user hierarchy on rows with the appropriate attribute hierarchy to avoid problems with attribute relations. In this case, that would be the [Date].[Month of Year] hierarchy.
2. Create a new calculated member in the [Date].[Month of Year] hierarchy and name it Last week. The definition of that member should include the 48th week, the last week with the data, like this:

```
MEMBER [Date].[Month of Year].[All Periods].[Last week] AS
  ( [Date].[Calendar Week of Year].&[48],
    [Date].[Month of Year].[All Periods] )
```

3. Include that member in rows as well and run the query, which should look like this:

```
WITH
MEMBER [Date].[Month of Year].[All Periods].[Last week] AS
  ( [Date].[Calendar Week of Year].&[48],
    [Date].[Month of Year].[All Periods] )
SELECT
  { [Measures].[Reseller Sales Amount] } ON 0,
NON EMPTY
  { [Date].[Month of Year].[Month of Year].MEMBERS,
    [Date].[Month of Year].[All Periods].[Last week] } ON 1
FROM
  [Adventure Works]
WHERE
  ( [Date].[Calendar Year].&[2013] )
```

4. Verify that the result includes the new calculated member in the last row, as in the following screenshot:

	Reseller Sales Amount
January	\$4,212,971.51
February	\$4,047,574.04
March	\$2,282,115.88
April	\$3,483,161.40
May	\$3,510,948.73
June	\$1,662,547.32
July	\$2,699,300.79
August	\$2,738,653.62
September	\$2,206,725.22
October	\$3,314,600.78
November	\$3,416,234.85
Last week	\$3,416,234.85

How it works...

Different hierarchies don't add up in columns, they cross join and form multiple columns. To combine members from different hierarchies into the same column, we need to resolve the dimensionality issue first. In our example, we have chosen to display the top five months from the [Date]. [Month of Year] hierarchy. This hierarchy has become our *host* hierarchy. Our trick is to create a calculated member in this *host* hierarchy that points to a member in another hierarchy, [Date]. [Calendar Week of Year]. We named this new calculated member [Last week], which is hosted in the [Date]. [Month of Year] hierarchy, off the root member [All Periods]. Once the months and the last week have the same dimensionality, we can now have a single column for the result because we are only using one hierarchy.

Choosing a *host* hierarchy and forcing all the members into the same dimensionality is our first task. Notice that we also provided a tuple, not just a plain reference to the other hierarchy's member. This tuple, repeated, is formed using the root member of the “host” hierarchy, [All Periods], as follows:

```
( [Date].[Calendar Week of Year].&[48],  
  [Date].[Month of Year].[All Periods] )
```

Why do we need to provide a tuple? Every expression is evaluated in its context. The current member of the [Date].[Month of Year] hierarchy is each month on the rows. Each single month of the year has no intersection with the 48th week (or any other week), and hence the result of the expression without the root member in that tuple would return null. By forcing the root member into the tuple, we are saying we do not want the members from the month of the year to interfere in the context. We are overriding the implicit query context in that expression with an explicit reference to the root member of the *host* hierarchy.

We need to validate our result before we wrap up this recipe. We have noticed that the result for the Last week member is the same as the result of the November member. Let us run the following query to validate this. This query simply cross joins two hierarchies; the Date and the Calendar Week of Year hierarchy. It shows us that the 48th week started on November 24, and November 29 is the last date that has a sales amount. No wonder the month November and the last week have the same result; they both contain only that week's data (which can be verified if you scroll up in the result window or uncomment the NON EMPTY part of the query):

```
SELECT  
    { [Measures].[Reseller Sales Amount] } ON 0,  
    --NON EMPTY  
    { [Date].[Date].[Date].MEMBERS *  
      [Date].[Calendar Week of Year]  
        .[Calendar Week of Year]  
        .MEMBERS  
    } ON 1  
FROM  
    [Adventure Works]  
WHERE  
    ( [Date].[Calendar Year].&[2013] )
```

		Reseller Sales Amount
November 24, 2013	CY Week 48	(null)
November 25, 2013	CY Week 48	(null)
November 26, 2013	CY Week 48	(null)
November 27, 2013	CY Week 48	(null)
November 28, 2013	CY Week 48	\$755.78
November 29, 2013	CY Week 48	\$3,415,479.07
November 30, 2013	CY Week 48	(null)
December 1, 2013	CY Week 49	(null)
December 2, 2013	CY Week 49	(null)
December 3, 2013	CY Week 49	(null)
December 4, 2013	CY Week 49	(null)

There's more...

In our initial query, we used a user hierarchy: the [Calendar] hierarchy. However, in our final solution query, we used two attribute hierarchies: the [Month of Year] and the [Calendar Week of Year]. The reason is that we need to take advantage of the attribute relations. The Date dimension is a very complex dimension with many related and unrelated attributes. It is a very challenging task to provide the proper tuple when the user hierarchy [Calendar] is on the rows in the original query because of all the relations among the members in the slicer, members on query axes, and the calculated member. A user hierarchy [Month of Year], on the other hand, requires that we use its root member only inside the tuple.

You should always look for a way to combine attribute hierarchies, not user hierarchies, whenever you are in a situation that requires that you to combine two hierarchies in one column. The color and size on the Product dimension is another example of two attribute hierarchies that we can combine into one column by using the technique in this recipe.

Use it, but don't abuse it

If it has been explicitly stated that the report should combine different hierarchies in a single column, we can reach for this solution. It's a rarity, but it is possible. In all other cases, a much better solution is to have each hierarchy in its own column.

Limitations

Besides the aforementioned limitation with user hierarchies, there is another one. When more than one member should be *hosted* in the other hierarchy, all of them should be defined as calculated members, one by one. This can be an administrative burden and so it is advised that this solution is used only in cases with a few members to be projected on the other hierarchy. Naturally, the hierarchy with more elements to be shown in the report should be the *hosting* one.

Finding the name of a child with the best/worst value

Sometimes, there is a need to perform a `for-each` loop to get the top or bottom members in the inner hierarchy for each member in the outer hierarchy. The *Identifying the best/worst members for each member of another hierarchy* recipe deals with exactly that kind of topic.

Following the theme of the recipes in this chapter of reducing the size of a report to a manageable level, in this recipe we will show you another possibility of how to reduce the size of the result – by showing not all the descendant members, but only the best child member. We will demonstrate how to identify the member with the best/worst value, only this time the member is not just from any other hierarchy, it will be from its children. We do not need the best/worst value from the child, and we are only going to return the name of the child in a calculated measure.

In our example, we will use the Product dimension. For every product subcategory, we are going to find the name of the product that has the best Internet sales amount.

Getting ready

Start SQL Server Management Studio and connect to your SSAS 2016 instance. Click on the **New Query** button and check that the target database is Adventure Works DW 2016.

In this example, we're going to use the Product dimension. Here is the query we will start from:

```
WITH
MEMBER [Measures].[Subcategory] AS
    iif( IsEmpty([Measures].[Internet Sales Amount] ),
        null,
        [Product].[Product Categories].CurrentMember.Parent.Name )
SELECT
    { [Measures].[Subcategory],
      [Measures].[Internet Sales Amount] } ON 0,
NON EMPTY
    { Descendants( [Product].[Product Categories].[Category],
                    2, SELF_AND_BEFORE ) } ON 1
FROM
    [Adventure Works]
```

Once executed, the query returns the values of the Internet Sales Amount measure for every Product and Subcategory. Part of the result is shown in the following screenshot. The measure serves as a validation point for each product and subcategory. That result can be used later for verification purposes:

	Subcategory	Internet Sales Amount
Accessories	All Products	\$700,759.96
Bike Racks	Accessories	\$39,360.00
Hitch Rack - 4-Bike	Bike Racks	\$39,360.00
Bike Stands	Accessories	\$39,591.00
All-Purpose Bike Stand	Bike Stands	\$39,591.00
Bottles and Cages	Accessories	\$56,798.19
Mountain Bottle Cage	Bottles and Cages	\$20,229.75
Road Bottle Cage	Bottles and Cages	\$15,390.88
Water Bottle - 30 oz.	Bottles and Cages	\$21,177.56
Cleaners	Accessories	\$7,218.60
Bike Wash - Dissolver	Cleaners	\$7,218.60

How to do it...

Follow these steps to return the best product's name for each product subcategory:

1. Modify the query so that it returns only subcategories on rows. In other words, specify 1 and SELF as arguments of the Descendants() function.
2. Remove the first calculated measure from the query.
3. Define a new calculated member and name it Best child. Its definition should test whether we are on a leaf member or not. If so, we should provide null.
4. If not, we should again test whether the Internet Sales Amount is null. If so, we should provide null. Otherwise, we should calculate the top one child based on the measure Internet Sales Amount and return the name of that child.
5. Include that calculated measure on columns as the second measure.
6. The final query should look like this:

```
WITH
MEMBER [Measures].[Best child] AS
    iif( IsLeaf( [Product].[Product Categories]
        .CurrentMember ),
        null,
        iif( IsEmpty([Measures].[Internet Sales Amount] ),
            null,
            TopCount( [Product].[Product Categories]
                .CurrentMember.Children,
                1,
                [Measures].[Internet Sales Amount]
            ) .Item(0).Name
        )
    )
SELECT
    { [Measures].[Internet Sales Amount],
        [Measures].[Best child] } ON 0,
NON EMPTY
    { Descendants( [Product].[Product Categories]
        .[Category], 1, SELF ) } ON 1
FROM
    [Adventure Works]
```

7. The results will look like this:

	Internet Sales Amount	Best child
Bike Racks	\$39,360.00	Hitch Rack - 4-Bike
Bike Stands	\$39,591.00	All-Purpose Bike Stand
Bottles and Cages	\$56,798.19	Water Bottle - 30 oz.
Cleaners	\$7,218.60	Bike Wash - Dissolver
Fenders	\$46,619.58	Fender Set - Mountain
Helmets	\$225,335.60	Sport-100 Helmet, Red
Hydration Packs	\$40,307.67	Hydration Pack - 70 oz.
Tires and Tubes	\$245,529.32	HL Mountain Tire
Mountain Bikes	\$9,952,759.56	Mountain-200 Black, 42
Road Bikes	\$14,520,584.04	Road-150 Red, 48
Touring Bikes	\$3,844,801.05	Touring-1000 Blue, 46
Caps	\$19,688.10	AWC Logo Cap
Gloves	\$35,020.70	Half-Finger Gloves, M
Jerseys	\$172,950.68	Long-Sleeve Logo Jersey, L
Shorts	\$71,319.81	Women's Mountain Shorts, L
Socks	\$5,106.32	Racing Socks, M
Vests	\$35,687.00	Classic Vest, M

How it works...

Leaf members don't have children. That's why we provided a branch in the definition of the calculated member and eliminated them from the start by returning a NULL value.

In the case of a non-leaf member, that is, a subcategory, a single child product with the highest measure is returned using the `TopCount()` function. We only returned the child's name by first retrieving the only member using the `.Item(0)` function and then using the `.Name` function.

The inner `iif()` function took care of empty values and preserved them as empty whenever the initial measure, the Internet Sales Amount measure, was null. This way, the `NON EMPTY` operator could exclude the same number of empty rows as in the initial query.

There's more...

Now that we have the name of the best child, we can include additional information.

For example, the following query shows how to display the child's value as well as its percentage:

```
WITH
MEMBER [Measures].[Best child] AS
    iif( IsLeaf( [Product].[Product Categories]
        .CurrentMember ),
        null,
        iif( IsEmpty([Measures].[Internet Sales Amount] ),
            null,
            TopCount( [Product].[Product Categories]
                .CurrentMember.Children,
                1, [Measures].[Internet Sales Amount]
            ).Item(0).Name
        )
    )
MEMBER [Measures].[Best child value] AS
    iif( IsLeaf( [Product].[Product Categories]
        .CurrentMember ),
        null,
        iif( IsEmpty([Measures].[Internet Sales Amount] ),
            null,
            ( TopCount( [Product].[Product Categories]
                .CurrentMember.Children,
                1, [Measures].[Internet Sales Amount]
            ).Item(0),
            [Measures].[Internet Sales Amount] )
        )
    )
    , FORMAT_STRING = 'Currency'
MEMBER [Measures].[Best child %] AS
    [Measures].[Best child value]
    /
    [Measures].[Internet Sales Amount]
    , FORMAT_STRING = 'Percent'
SELECT
```

```
{ [Measures].[Internet Sales Amount],  
  [Measures].[Best child],  
  [Measures].[Best child value],  
  [Measures].[Best child %] } ON 0,  
NON EMPTY  
{ Descendants( [Product].[Product Categories].[Category],  
  1, SELF ) } ON 1  
FROM  
[Adventure Works]
```

A child's value is obtained on the same principle as the child's name, except this time the tuple was used to get the value in that coordinate.

The percentage is calculated in a standard way.

Once executed, the preceding query returns this result:

	Internet Sales Amount	Best child	Best child value	Best child %
Bike Racks	\$39,360.00	Hitch Rack - 4-Bike	\$39,360.00	100.00%
Bike Stands	\$39,591.00	All-Purpose Bike Stand	\$39,591.00	100.00%
Bottles and Cages	\$56,798.19	Water Bottle - 30 oz.	\$21,177.56	37.29%
Cleaners	\$7,218.60	Bike Wash - Dissolver	\$7,218.60	100.00%
Fenders	\$46,619.58	Fender Set - Mountain	\$46,619.58	100.00%
Helmets	\$225,335.60	Sport-100 Helmet, Red	\$78,027.70	34.63%
Hydration Packs	\$40,307.67	Hydration Pack - 70 oz.	\$40,307.67	100.00%
Tires and Tubes	\$245,529.32	HL Mountain Tire	\$48,860.00	19.90%
Mountain Bikes	\$9,952,759.56	Mountain-200 Black, 42	\$979,960.73	9.85%
Road Bikes	\$14,520,584.04	Road-150 Red, 48	\$1,205,876.99	8.30%
Touring Bikes	\$3,844,801.05	Touring-1000 Blue, 46	\$421,980.39	10.98%
Caps	\$19,688.10	AWC Logo Cap	\$19,688.10	100.00%
Gloves	\$35,020.70	Half-Finger Gloves, M	\$12,220.51	34.90%
Jerseys	\$172,950.68	Long-Sleeve Logo Jersey, L	\$22,595.48	13.06%
Shorts	\$71,319.81	Women's Mountain Shorts, L	\$25,406.37	35.62%
Socks	\$5,106.32	Racing Socks, M	\$2,679.02	52.46%
Vests	\$35,687.00	Classic Vest, M	\$12,636.50	35.41%

Variations on a theme

Using the same principle, it is possible to get the member with the worst value. We have to be careful and apply `NonEmpty()` first to ignore empty values, as explained in the *Isolating the worst N members in a set* recipe.

Displaying more than one member's caption

It is possible to display several names inside the same cell. If that is the case, we must use the `Generate()` function in conjunction with its third syntax to start the iteration. Once the iteration is in place, everything else remains the same.

See also

Refer to the following recipes in this chapter:

- *Isolating the best N members in a set*
- *Isolating the worst N members in a set*
- *Identifying the best/worst members for each member of another hierarchy*
- *Displaying a few important members, with the others as a single row, and the total at the end*

Highlighting siblings with the best/worst values

Data analysis becomes easier once we provide more information than a simple black and white grid allows us to. One way of doing this is to color code some cells. In this recipe, we will show you how to highlight cells with the minimum and the maximum values among siblings and how to color code them based on their values relative to their siblings' values.

Getting ready

Start SQL Server Management Studio and connect to your SSAS 2016 instance. Click on the **New Query** button and check that the target database is Adventure Works DW 2016.

In this example, we are going to use the Product dimension. Here is the query we'll start from:

```
SELECT
    { [Measures].[Internet Sales Amount] } ON 0,
NON EMPTY
    { Descendants( [Product].[Product Categories].[Category],
        1, SELF ) } ON 1
FROM
    [Adventure Works]
```

Once executed, the query returns the value of the Internet Sales Amount measure for every single product subcategory. Part of the result is shown in the following screenshot. We have two goals: one is to find the category that each subcategory belongs to; the other is to color code the best and worst subcategories in each category:

	Internet Sales Amount
Bike Racks	\$39,360.00
Bike Stands	\$39,591.00
Bottles and Cages	\$56,798.19
Cleaners	\$7,218.60
Fenders	\$46,619.58
Helmets	\$225,335.60
Hydration Packs	\$40,307.67
Tires and Tubes	\$245,529.32
Mountain Bikes	\$9,952,759.56
Road Bikes	\$14,520,584.04
Touring Bikes	\$3,844,801.05
Caps	\$19,688.10
Gloves	\$35,020.70
Jerseys	\$172,950.68
Shorts	\$71,319.81
Socks	\$5,106.32
Vests	\$35,687.00

How to do it...

Follow these steps to color code the best and worst subcategories in each category:

1. Define a calculated measure that will show the name of the parent for each subcategory. Name it Category.
2. Be sure to provide the null value whenever the initial measure is null and then include that measure on columns as well, as with the first of the two.
3. Define a cell calculation for the Internet Sales Amount measure and name it Highlighted Amount.
4. Define the BACK_COLOR property for the Highlighted Amount cell calculation. Use an expression that tests whether the current value is a max/min value.
5. Provide the adequate RGB values: green for max, red for min, and null for everything else.
6. Include the CELL PROPERTIES required to display the color information of a cell at the end of the query.
7. When everything is done, the query should look like this:

```
WITH
MEMBER [Measures].[Category] AS
    iif( IsEmpty( [Measures].[Internet Sales Amount] ),
        null,
        [Product].[Product Categories]
        .CurrentMember.Parent.Name )
CELL CALCULATION [Highlighted Amount]
FOR '{ [Measures].[Internet Sales Amount] }' AS
    [Measures].[Internet Sales Amount]
, BACK_COLOR =
    iif( [Measures].CurrentMember =
        Max( [Product].[Product Categories]
            .CurrentMember.Siblings,
            [Measures].CurrentMember ),
        RGB(128,242,128), // green
        iif( [Measures].CurrentMember =
            Min( [Product].[Product Categories]
                .CurrentMember.Siblings,
                [Measures].CurrentMember ),
            RGB(242,128,128), // red
            null )
    )
SELECT
    { [Measures].[Category],
        [Measures].[Internet Sales Amount] } ON 0,
NON EMPTY
```

```
{ Descendants( [Product].[Product Categories]
    .[Category], 1, SELF ) } ON 1
FROM
    [Adventure Works]
CELL PROPERTIES
    VALUE,
    FORMATTED_VALUE,
    FORE_COLOR,
    BACK_COLOR
```

8. Once executed, the query returns the result presented on the following screenshot:

	Category	Internet Sales Amount
Bike Racks	Accessories	\$39,360.00
Bike Stands	Accessories	\$39,591.00
Bottles and Cages	Accessories	\$56,798.19
Cleaners	Accessories	\$7,218.60
Fenders	Accessories	\$46,619.58
Helmets	Accessories	\$225,335.60
Hydration Packs	Accessories	\$40,307.67
Tires and Tubes	Accessories	\$245,529.32
Mountain Bikes	Bikes	\$9,952,759.56
Road Bikes	Bikes	\$14,520,584.04
Touring Bikes	Bikes	\$3,844,801.05
Caps	Clothing	\$19,688.10
Gloves	Clothing	\$35,020.70
Jerseys	Clothing	\$172,950.68
Shorts	Clothing	\$71,319.81
Socks	Clothing	\$5,106.32
Vests	Clothing	\$35,687.00

9. Notice that the highest value in a category is highlighted with light green and the lowest value per category is highlighted with light red. That's the visual cue we're after.

How it works...

Siblings are members that are under the same parent. In our earlier result, the first eight subcategories are all siblings that are under one category: Accessories. We deliberately created a calculated measure [Measures].[Category] using the .Parent function. We can now visually identify all the siblings under each category, and can validate our color-coding calculation.

The BACK_COLOR property controls the color of the background of a cell. It can be defined as a constant value, but it can also be an expression. In this case, we used a combination – conditional formatting using fixed values for two colors: light green and light red.

We had to use the `iif()` function in the definition of the calculated measure [Measures].[Category] because a calculated measure is evaluated as a string, which is never null. Therefore, we have bound the calculated measure to the original measure [`Internet Sales Amount`] so that it returns values only for rows with data.

In the BACK_COLOR property expression, we used two nested `iif()` functions, with the `Max()` function in the outer `iif()` and `Min()` function in the inner `iif()`. The `Max()` and `Min()` functions return the highest and the lowest value in the specified set of sibling members. The current measure's value, which is the sales amount for each subcategory, is compared to the maximum and minimum values, respectively. In case of a match, the appropriate color is chosen (green for max and red for min values).

Finally, because the measure `Internet Sales Amount` already existed, we used the CELL CALCULATION syntax to define (or overwrite) additional properties for it, such as the BACK_COLOR property in this example. The CELL CALCULATION is one of the three elements that can be defined in the WITH part of the query. It is analogous to the SCOPE statement inside the MDX script. In other words, it can be used to define or overwrite a value inside a subcube or to define or overwrite cell properties such as BACK_COLOR.

There's more...

It is also possible to color code any measure in a different way. For example, it is possible to provide a range of colors so that the cell with the highest value has one color, the cell with the lowest value another color, and those in between a gradient of those colors. See for yourself by running this query and observing the result afterwards:

```
WITH  
MEMBER [Measures].[Category] AS  
    iif( IsEmpty( [Measures].[Internet Sales Amount] ),
```

```
        null,
        [Product].[Product Categories]
        .CurrentMember.Parent.Name )
MEMBER [Measures].[Rank in siblings] AS
    iif( IsEmpty( [Measures].[Internet Sales Amount] ),
        null,
        Rank( [Product].[Product Categories].CurrentMember,
            NonEmpty( [Product].[Product Categories]
            .CurrentMember.Siblings,
            [Measures].[Internet Sales Amount] ),
            [Measures].[Internet Sales Amount] )
        )
MEMBER [Measures].[Count of siblings] AS
    Sum( [Product].[Product Categories]
    .CurrentMember.Siblings,
    iif( IsEmpty( [Measures].[Internet Sales Amount] ),
        null, 1 )
    )
MEMBER [Measures].[R] AS
    iif( IsEmpty( [Measures].[Internet Sales Amount] ),
        null,
        255 / ( [Measures].[Count of siblings] - 1 ) *
        ( [Measures].[Count of siblings] -
        [Measures].[Rank in siblings] ) ) -- all shades
    , FORMAT_STRING = '#,#'
    , VISIBLE = 1
MEMBER [Measures].[G] AS
    iif( IsEmpty( [Measures].[Internet Sales Amount] ),
        null, 0 ) -- fixed dark green
    , VISIBLE = 1
MEMBER [Measures].[B] AS
    iif( IsEmpty( [Measures].[Internet Sales Amount] ),
        null,
        100 / [Measures].[Count of siblings] *
        [Measures].[Rank in siblings] ) -- dark shades
    , FORMAT_STRING = '#,#'
    , VISIBLE = 1
CELL CALCULATION [Highlighted Amount]
FOR '{ [Measures].[Internet Sales Amount] }' AS
    [Measures].[Internet Sales Amount]
    , BACK_COLOR = RGB( [Measures].[R],
                        [Measures].[G],
                        [Measures].[B] )
    , FORE_COLOR = RGB( 255, 255, 255 ) -- white
SELECT
{ [Measures].[Category],
[Measures].[Rank in siblings],
[Measures].[Internet Sales Amount],
```

```
[Measures].[R],  
[Measures].[G],  
[Measures].[B] } ON 0,  
NON EMPTY  
{ Descendants( [Product].[Product Categories].[Category],  
1, SELF ) } ON 1  
FROM  
[Adventure Works]  
CELL PROPERTIES  
VALUE,  
FORMATTED_VALUE,  
FORE_COLOR,  
BACK_COLOR
```

The previous query, once executed, returns the result presented in the following screenshot:

	Category	Rank in siblings	Internet Sales Amount	R	G	B
Bike Racks	Accessories	7	\$39,360.00	36	0	88
Bike Stands	Accessories	6	\$39,591.00	73	0	75
Bottles and Cages	Accessories	3	\$56,798.19	182	0	38
Cleaners	Accessories	8	\$7,218.60	(null)	0	100
Fenders	Accessories	4	\$46,619.58	146	0	50
Helmets	Accessories	2	\$225,335.60	219	0	25
Hydration Packs	Accessories	5	\$40,307.67	109	0	63
Tires and Tubes	Accessories	1	\$245,529.32	255	0	13
Mountain Bikes	Bikes	2	\$9,952,759.56	128	0	67
Road Bikes	Bikes	1	\$14,520,584.04	255	0	33
Touring Bikes	Bikes	3	\$3,844,801.05	(null)	0	100
Caps	Clothing	5	\$19,688.10	51	0	83
Gloves	Clothing	4	\$35,020.70	102	0	67
Jerseys	Clothing	1	\$172,950.68	255	0	17
Shorts	Clothing	2	\$71,319.81	204	0	33
Socks	Clothing	6	\$5,106.32	(null)	0	100
Vests	Clothing	3	\$35,687.00	153	0	50

The Category calculated measure is the same as in the previous query.

Rank in siblings is a measure that returns the rank of an individual subcategory when compared with the results of its siblings. This measure is included in the columns so that the verification becomes relatively easy.

The Count of siblings is a measure which returns the number of sibling members and is used to establish the boundaries as well as the increment in the color gradient.

The R, G, and B values are calculated measures used to define the background color for the Internet Sales Amount measure. The gradient is calculated using the combination of rank and count measures with additional offsets so that the colors look better (keeping them relatively dark). In addition to that, the FORE_COLOR property is set to white so that proper contrast is preserved. The three calculated measures are displayed last in the result just to show how the values change. You can freely hide those measures and remove them from the columns axis. The VISIBLE property is there to remind you about that.

It's worth mentioning that one component of the color should decrease as the other increases. Here, it is implemented with the rank and count-rank expressions. As one increases, the other decreases.

For more complex color-coding, an appropriate stored procedure installed on the SSAS server is another solution - unless the frontend and its pivot table grid already supports these features.

Troubleshooting

Don't forget to include the required cell properties, namely BACK_COLOR and FORE_COLOR, or the recipe solution won't work. The same applies for the frontend you're using. If you don't see the effect, check whether there's an option to turn those cell properties on.

See also

- Refer to the *Implementing bubble-up exceptions* recipe

Implementing bubble-up exceptions

In the previous recipe, we dealt with highlighting cells based on their results in comparison with sibling members, which can be visualized in a horizontal direction. In this recipe, we will take a look at how to do the same but in a vertical direction, using the descendants of members in the report.

Bubble-up exceptions are a nice way of visualizing information about the descendants of a member without making reports too big. By coding the information about the result of descendants, we can have compact reports on a higher level, while still having some kind of information about what's going on below.

The information we are going to bubble-up will be presented by color-coding the cells.

Getting ready

Start SQL Server Management Studio and connect to your SSAS 2016 instance. Click on the **New Query** button and check that the target database is Adventure Works DW 2016.

In this example, we're going to use the `Product` dimension. Here is the query we'll start from:

```
SELECT
    { [Measures].[Reseller Sales Amount],
      [Measures].[Reseller Gross Profit Margin] } ON 0,
NON EMPTY
    { Descendants( [Product].[Product Categories].[Category],
      1, BEFORE ) } ON 1
FROM
    [Adventure Works]
WHERE
    ( [Date].[Fiscal].[Fiscal Year].&[2013] )
```

Once executed, the query returns the value of the `Reseller Sales Amount` and `Reseller Gross Profit Margin` measures in the fiscal year 2013 for each product category.

We are going to analyze the product subcategory, which is the descendant of the product category, and color-code the category if at least one of its subcategories has a negative profit margin. We will do this in one query without displaying the subcategories.

How to do it...

Follow these steps to color code the product categories if at least one of its subcategories has a negative profit margin:

1. Create a new calculated measure that will serve as an alias for the `Reseller Gross Profit Margin` measure. Name it `Margin with Bubble-up`.

2. Define the FORE_COLOR property of that measure so that it turns red when at least one descendant on the lower level has negative values for the margin.
3. Include that new measure on the columns, as with the third measure there.
4. Include the CELL PROPERTIES part of the query and enlist the FORE_COLOR property as one of them to be returned by the query.
5. Execute the query, which should look like this:

```
WITH
MEMBER [Measures].[Margin with Bubble-up] AS
    [Measures].[Reseller Gross Profit Margin]
    , FORE_COLOR =
        iif(
            Min( Descendants( [Product].[Product Categories]
                .CurrentMember,
                1, SELF ),
            [Measures].CurrentMember ) < 0,
            RGB( 255, 0, 0 ), -- red
            null
        )
SELECT
    { [Measures].[Reseller Sales Amount],
        [Measures].[Reseller Gross Profit Margin],
        [Measures].[Margin with Bubble-up] } ON 0,
NON EMPTY
    { Descendants( [Product].[Product Categories]
        .[Category], 1, BEFORE ) } ON 1
FROM
    [Adventure Works]
WHERE
    ( [Date].[Fiscal].[Fiscal Year].&[2013] )
CELL PROPERTIES
    VALUE,
    FORMATTED_VALUE,
    FORE_COLOR,
    BACK_COLOR
```

6. Verify that the new measure is red in three rows: **Bikes**, **Clothing** and **Components**:

	Reseller Sales Amount	Reseller Gross Profit Margin	Margin with Bubble-up
Accessories	\$145,072.26	36.64%	36.64%
Bikes	\$11,946,118.47	-1.92%	-1.92%
Clothing	\$341,439.51	8.83%	8.83%
Components	\$1,942,885.03	6.59%	6.59%

How it works...

As mentioned earlier, this new measure is just an alias for the original measure, [Reseller Gross Profit Margin]; there's nothing special in its definition. Its real value is in the additional cell property expressions, namely the FORE_COLOR property used in this example. It could have been the BACK_COLOR property if we preferred it; what matters in this recipe is the expression we used in the conditional color-coding of the calculated measure.

In that expression, we are analyzing descendants of the current member and extracting only the ones with a negative result for the current measure: the Margin with Bubble-up measure. As that measure is an alias for the Reseller Gross Profit Margin measure, we are actually testing the latter measure.

We applied the Min() function to the tuple and used the outer iif() function to determine whether the minimum Reseller Gross Profit Margin is a negative value. If that's a negative number, we turn the color to red. If not, we leave it as it is.

The red color for the three rows, **Bikes**, **Clothing** and **Components**, tells us that at least one of the subcategories under them has a negative profit margin. That might have been obvious for **Bikes**, but not for the other two categories since their margin is positive.

There's more...

On the query axis on the rows, we could have directly used the level [Category] without using the construct Descendants([Product].[Product Categories].[Category], 1, BEFORE), which is essentially just another way of specifying that we want to see product categories. However, the advantage of this construct is that it allows us to make a small change in the query, maybe using a report parameter, and to be able to drill down one level below.

The part that needs a change is the second argument of the Descendants() function on the rows. The value of that argument was 1, signaling that we want only product categories and nothing else.

If we change that argument to 2, we will get the result as displayed in the following screenshot:

	Reseller Sales Amount	Reseller Gross Profit Margin	Margin with Bubble-up
Accessories	\$145,072.26	36.64%	36.64%
Bike Racks	\$70,955.69	36.69%	36.69%
Bottles and Cages	\$2,612.04	36.48%	36.48%
Cleaners	\$3,892.42	36.45%	36.45%
Helmets	\$45,546.01	36.56%	36.56%
Hydration Packs	\$21,776.19	36.72%	36.72%
Tires and Tubes	\$289.91	37.66%	37.66%
Bikes	\$11,946,118.47	-1.92%	-1.92%
Mountain Bikes	\$3,474,835.39	5.86%	5.86%
Road Bikes	\$3,914,756.73	-6.55%	-6.55%
Touring Bikes	\$4,556,526.35	-3.87%	-3.87%
Clothing	\$341,439.51	8.83%	8.83%
Caps	\$5,016.64	-31.09%	-31.09%
Gloves	\$14,730.31	37.45%	37.45%
Jerseys	\$131,884.94	-30.36%	-30.36%
Shorts	\$101,797.63	34.43%	34.43%
Socks	\$6,599.12	35.90%	35.90%
Vests	\$81,410.86	35.38%	35.38%
Components	\$1,942,885.03	6.59%	6.59%
Bottom Brackets	\$19,284.10	26.00%	26.00%
Brakes	\$19,170.00	26.00%	26.00%
Chains	\$3,400.32	26.00%	26.00%
Cranksets	\$72,743.74	26.00%	26.00%
Derailleurs	\$23,967.07	25.88%	25.88%
Handlebars	\$26,897.54	26.00%	26.00%
Mountain Frames	\$812,831.04	8.73%	8.73%
Pedals	\$49,824.33	25.91%	25.91%
Road Frames	\$333,091.84	-1.13%	-1.13%
Saddles	\$16,840.18	25.96%	25.96%
Touring Frames	\$564,834.87	0.10%	0.10%

In other words, now the query includes both product categories and product subcategories on rows.

What's good about this is that our measure reacts in this scenario as well. Three subcategories, **Bikes**, **Clothing** and **Components**, remained in red. The change also captures a few more negative values. The color-coding calculation not only captured the descendants that had negative values, but also any member itself that was negative.

The reason this worked is because our color-coding expression for our calculated measure also used a relative depth for descendants. The `Descendants` expression is repeated here. The relative depth we used was 1:

```
Descendants( [Product].[Product Categories].CurrentMember,  
             1, SELF )
```

If it is required, we can specify an absolute level, not a relative one. We would do this by specifying the name of a particular level instead of the number. For example, if we want our expression to only detect negative values in the subcategories, we should specify it like this:

```
Descendants( [Product].[Product Categories].CurrentMember,  
             [Product].[Product Categories].[Subcategory],  
             SELF )
```

If we want the expression to work on only the lowest level, we should use this construct:

```
Descendants( [Product].[Product Categories].CurrentMember, ,  
             LEAVES )
```

In short, there are a lot of possibilities and you are free to experiment.

Practical value of bubble-up exceptions

Members colored in red signal that some of the members on the lower level have negative margins. With the visual indicator, end users can save a lot of their precious time by drilling down to the next level when a cell gives them a visual clue. On the other hand, without the visual indicator, they might miss opportunities if data at a more granular level is not examined.

Potential problems

On very large hierarchies, there can be problems with performance if the bubble-up exceptions are set at a granular level that is too low.

5

Navigation

In this chapter, we will cover the following recipes:

- Detecting a particular member in a hierarchy
- Detecting the root member
- Detecting members on the same branch
- Finding related members in the same dimension
- Finding related members in another dimension
- Calculating various percentages
- Calculating various averages
- Calculating various ranks

Introduction

One of the advantages of multidimensional cubes is their rich metadata model backed up with a significant number of MDX functions that enable easy navigation and data retrieval from any part of the cube. We can easily navigate through levels, hierarchies, dimensions, and cubes.

The goal of this chapter is to show common tasks and techniques related to navigation and data retrieval relative to the current context. We will show how to take control of and finetune the query context and how to achieve query optimization.

The first three recipes illustrate how to test whether the current context is the one we're expecting or not.

Then we will continue on to two recipes where we illustrate how to find related members, whether the related members are on different hierarchies in the same dimension, or they are from totally different dimensions.

Finally, building on the knowledge of detecting specific members and navigating through any parts of the cube, we will run a series of relative calculations of percentage, average, and rank. We provide examples for relative calculations that take the current context and compare its value to some other related context, such as parents, children, siblings, members on the same level or same hierarchy, and so on. Examples of such calculations are percentage of parent, percentage of total, average on a level, average on leaves, rank among siblings, rank on a level, and so on.

Multidimensional cubes are conceptually enormous structures filled with empty space, with no data at all in all but a few combinations. There are times when the Analysis Services engine takes care of that by utilizing various algorithms that compact the cube space, but there are times when we have to do that by ourselves.

The MDX language incorporates functions that enable fast retrieval of related members, to move from one hierarchy to another, from one dimension to another, and to get only members valid in the current context. This technique improves query performance because the engine is not forced to calculate on non-relevant space. There are several recipes in this chapter covering that topic.

Let's start!

Detecting a particular member in a hierarchy

We frequently encounter situations where we need to include or exclude a certain member in a calculation. Our first step is to determine whether the member exists in a hierarchy.

When iterating through a set of hierarchy members, at each step in the iteration, the member being operated upon is the current member. This recipe shows how to determine whether the current member in the query context is a particular member that we are interested in.

Getting ready

Start SQL Server Management Studio and connect to your SSAS 2012 instance. Click on the **New Query** button and check that the target database is Adventure Works DW 2012.

In this example, we're going to use the `Product` dimension. Here's the query we'll start from:

```
SELECT
    { } ON 0,
    { [Product].[Color].AllMembers } ON 1
FROM
    [Adventure Works]
```

Once executed, the query returns all product colors, including the root member. The preceding query will return products in rows, with nothing in columns. This type of query that has nothing on columns is explained in the *Skipping axis* recipe in Chapter 1, *Elementary MDX Techniques*:

All Products
Black
Blue
Grey
Multi
NA
Red
Silver
Silver/Black
White
Yellow

Our task is to detect the member **NA**. Once the specific member is detected, we can perform calculations that either include this member or exclude this member. In this recipe, we are focusing only on how to perform the detection.

How to do it...

Follow these steps to detect the NA member:

1. Add the WITH block of the query.
2. Create a new calculated measure and name it Member is detected.
3. Define it as True for the NA member and null, not False, in all other cases.
4. Add this calculated measure on axis 0.
5. Execute the query, which should look like this:

```
WITH
MEMBER [Measures].[Member is detected] AS
    iif( [Product].[Color].CurrentMember Is
        [Product].[Color].&[NA],
        True,
        null
    )
SELECT
    { [Measures].[Member is detected] } ON 0,
    { [Product].[Color].AllMembers } ON 1
FROM
    [Adventure Works]
```

6. Verify that the result matches the following screenshot:

	Member is detected
All Products	(null)
Black	(null)
Blue	(null)
Grey	(null)
Multi	(null)
NA	True
Red	(null)
Silver	(null)
Silver/Black	(null)
White	(null)
Yellow	(null)

How it works...

When an MDX query is executed, part of the standard query execution is iterating through a set of hierarchy members on query axes. The current member changes on a hierarchy used on an axis in a query. In the iteration phase, we can detect the current context on an axis in the query using the `CurrentMember` function. This function returns the member of the hierarchy on the query axis we are currently operating upon.

The `IS` operator performs a logical comparison on two object expressions, and is often used to determine whether two tuples or members are exactly equivalent. By comparing the current member with a particular member of the same hierarchy, we can know when we have hit the row or column with that member in it.

There's more...

The solution presented here is good in situations when there is a *temporary* need to isolate a particular member in the query. The emphasis is on the word *temporary*. Typical examples of this type of temporary need include highlighting the rows or columns of a report or providing two calculations for a single measure based on the context.

In cases where the required behavior has a more *permanent* characteristic, defining the member in MDX script or using the `Scope()` statement are better approaches.

Take a look at the following script, which can be added in the MDX script of the Adventure Works cube:

```
Create Member CurrentCube.[Measures].[Member is detected]
As null;

Scope( ([Product].[Color].&[NA],
        [Measures].[Member is detected] ) );
    This = True;
End Scope;
```

First, the measure is defined as `null`. Then, the scope is applied to it in the context of NA color. When the scope becomes active, it will provide `True` as the result. In all other cases, the initial definition of the measure `null` will prevail.

The `Scope()` statement is basically doing the same thing as the `iif()` statement in a calculated member, with one important difference—the scope statement itself is evaluated (resolved) only once, when the first user connects to the cube. That goes for named sets and the left side of assignments too, which can easily be verified by observing the *Execute MDX Script Begin/End* events in SQL Server Profiler. More about this is in the *Capturing MDX queries generated by SSAS frontends* recipe in Chapter 10, *On the Edge*.

The right side of assignments (here, the value `True`) is evaluated at query time and hence it makes no difference whether the expression on that side was used in an MDX script or in a query. However, as the scope statement gets evaluated only once, it may be reasonable to put a complex expression in the scope instead of the `iif()` function.

Important remarks

The earlier `Create Member` statement did not use the Boolean value `False` as the result of the negative branch. Instead, the value of `null` was provided in order to keep the calculation sparse and hence preserve performance. The `iif()` function is optimized to work in block mode if one of the branches is `null`.

Comparing members versus comparing values

We have used the `Is` keyword to compare the current member on the `[Color]` hierarchy with `[Product]. [Color] .& [NA]`, which is a key-based fully qualified member on the same hierarchy. It is important to differentiate the comparison of members from the comparison of values. The first is performed using the `Is` keyword, the latter using the `=` sign. It is essential that you learn and understand that difference. Otherwise, you will not get correct results from your logical comparison.

When you do need to compare values using the `=` sign, try to compare members using their unique names whenever you can. The following logical comparison using the member's unique name is equivalent to using the `Is` keyword to compare two member object expressions:

```
[Product]. [Color].CurrentMember.Uniquename = '[Product]. [Color] .& [NA]'
```

We should avoid comparing member properties such as name. The following logical comparison will work, but it will not give you the best possible performance:

```
[Product]. [Color].CurrentMember.Name = 'NA'
```

The other reason you should avoid comparing names is that names can repeat, especially in multilevel user hierarchies. For example, the Geography.Geography hierarchy has New York the state and New York the city. Obviously, using the following code to compare the current member to that member by its name would be a bad choice:

```
[Geography]. [Geography].CurrentMember.name = 'New York'
```

Detecting complex combinations of members

When the business logic is complex, it might be required to detect several members, not just one of them. In that case, apply the same principles described in this recipe. Your only concern in that case is to handle the logic correctly. The MDX language offers various logical functions for that scenario.

In the case of OR logic, here are a few additional hints:

- You can define a set of members and use the `Intersect()` function to test whether the set formed from the current member has an intersection with the predefined set.
- In cases of poor performance, you might want to consider creating a new attribute hierarchy based on a Yes/No value in the field derived using the case statement in your DW/DSV, as explained in the *Using a new attribute to separate members on a level* recipe in Chapter 8, *When MDX Is Not Enough*. This way, you can have pre-aggregated values for those two members.
- In cases of very complex logic, you'd be better off defining a new column in your fact table and creating a dimension from it. That way, you are pushing the logic in DW and using SSAS cubes for what they do best—slicing and aggregation of the data.

See also

- The *Detecting the root member* recipe covers a similar topic, but in a much more narrow case. It is worth reading right after this recipe because of the additional insights it provides.

Detecting the root member

The root member is the topmost member of a hierarchy. It is present in all hierarchies (in user hierarchies as well as in attributes hierarchies) as long as the `IsAggregatable` property is enabled, as in its default state.

The root member represents the highest level of granularity within a hierarchy the data can be aggregated up to. When calculating the percentage of a total, we need to detect whether the current member in the query context is pointing to the root member of a hierarchy or not. Based on the detection result, we can make our calculation of the percentage of a total response different to that of the root member.

Although we have the real-world application of the root member detection in mind, this recipe shows only how to detect the root member.

Getting ready

Start SQL Server Management Studio and connect to your SSAS 2016 instance. Click on the **New Query** button and check that the target database is Adventure Works DW 2016.

In this example, we're going to use the same `Color` hierarchy of the `Product` dimension as in the previous recipe, *Detecting a particular member in a hierarchy*. Here's that query:

```
SELECT
    { } ON 0,
    { [Product].[Color].AllMembers } ON 1
FROM
    [Adventure Works]
```

Once executed, the query returns all product colors, including the root member. The preceding query will return products in rows, with nothing in columns. This special type of query is explained in the *Skipping axis* recipe in Chapter 1, *Elementary MDX Techniques*.

In the previous recipe, *Detecting a particular member in a hierarchy*, we showed you how to detect a member `NA`. Our task in this recipe is to detect the root member in the `[Color]` hierarchy.

How to do it...

Follow these steps to create a calculated member that detects the root member:

1. Add the WITH block of the query.
2. Create a new calculated measure and name it Root member detected.
3. Define it as True for the branch where the detection occurs and null for the other part.
4. Add this measure on axis 0.
5. Execute the query, which should look like this:

```
WITH
MEMBER [Measures].[Root member detected] AS
    iif( [Product].[Color].CurrentMember Is
        [Product].[Color].[All Products],
        True,
        null
    )
SELECT
    { [Measures].[Root member detected] } ON 0,
    { [Product].[Color].AllMembers } ON 1
FROM
    [Adventure Works]
```

7. Verify that the result matches the following screenshot:

	Root member detected
All Products	True
Black	(null)
Blue	(null)
Grey	(null)
Multi	(null)
NA	(null)
Red	(null)
Silver	(null)
Silver/Black	(null)
White	(null)
Yellow	(null)

How it works...

The `CurrentMember` function returns the member we are currently operating on in a particular hierarchy. We then compare this current member to the root member of the `[Color]` hierarchy, `[Product].[Color].[All Products]`, to detect whether the current member on the query axis is the root member.

The condition in our `iif()` expression evaluates to the Boolean value `True` when the root member is detected. In all other cases, the returned value is `null`.

There's more...

In the preceding query, we have hardcoded the root member, by referencing it as `[Product].[Color].[All Products]`. However, the name of the root member can change over time. We should try to avoid referencing the root member using its name.

Instead of using the reference to the root member, we can use the reference to its internal alias `All`. The calculated measure can be changed to this:

```
MEMBER [Measures].[Root member detected] AS
    iif( [Product].[Color].CurrentMember Is
        [Product].[Color].[All],
        True,
        null
    )
```

With the changed name of the root member to `[Product].[Color].[All]`, our calculation still works. That is because the internal alias name `[All]` for the root member works the same way as the actual name of the root member.

`[All]` is the internal alias for the root member. It all works the same way as the actual name of the root member. However, anything other than the correct name of the root member and its alias will result in an error. Depending on a particular configuration of SSAS cube, the error will be reported or bypassed. Mostly, it will be bypassed, because it is the default option of SSAS cube.

This trick will work on any hierarchy, but may not work in future SSAS versions, based on the fact that it isn't documented anywhere.

There are, of course, other ways to detect the root member. One is to test the level of a hierarchy by retrieving the ordinal number of the current member. The `Ordinal` function returns a zero-based ordinal value associated with a level. The calculated measure can be changed to this:

```
MEMBER [Measures].[Root member detected] AS  
    iif( [Product].[Color].CurrentMember.Level.Ordinal = 0,  
        True,  
        null  
    )
```

The ordinal value of a level in a hierarchy can be from 0 to n, where n is the number of userdefined levels in that hierarchy. An ordinal value of zero represents the topmost level, the root member.

One potential problem with this calculation is that any calculated member defined on the hierarchy itself (not on another regular member) will also be positioned on the topmost level. Its level ordinal will be zero too. However, if you exclude calculated members in our calculation, the preceding expression will work.

To avoid hardcoding the name of a root member, we have another way to detect the topmost regular member (as opposed to calculated members) using the `Root()` function. The calculated measure can be changed to this:

```
MEMBER [Measures].[Root member detected] AS  
    iif( [Product].[Color].CurrentMember Is  
        Extract(Root([Product]),  
        [Product].[Color]).item(0),  
        True,  
        null  
    )
```

In the preceding expression, we used the `Root()` function, which takes the dimension `[Product]` as the argument and returns a tuple that contains the top-level member (or the default member if the `All` member does not exist) from each attribute hierarchy in the `[Product]` dimension based on the context of the current member. Since we are only interested in the attribute hierarchy `[Color]`, we used the `Extract()` function to isolate the single hierarchy and its members in that tuple. The `Item()` function converts the set of members into a single member. That's the topmost regular member of that hierarchy extracted from the tuple.

The scope-based solution

All the calculations for [Root member detected] so far are query-based, being part of an MDX expression in MDX queries. In cases where the calculations are shared by many different users, sessions, and applications, we should define the calculation in MDX script, either using the `Scope()` statement or using the `CREATE MEMBER` statement only without the `Scope()` statement. This scope-based solution is a better approach than the query-based `iif()` statement.

The following MDX script is equivalent to the query-based calculation. Define it in the MDX script of the Adventure Works cube using SSDT, deploy, and then verify its result in the cube browser using the same hierarchy [Color]:

```
Create Member CurrentCube.[Measures].[Root member detected]
As null;

Scope( ([Product].[Color].[All],
        [Measures].[Root member detected] ) );
    This = True;
End Scope;
```

One more thing: detection of this kind is usually done so that another calculation can exploit it. In MDX script, it is possible to directly specify the scope for an existing measure, such as [Internet Sales Amount], and to provide a scope-based calculation for it. The following MDX script is an example that returns the average [Internet Sales Amount] for all colors at the topmost level using the `Scope()` statement to detect the All level:

```
Scope( ([Product].[Color].[All],
        [Measures].[Internet Sales Amount] ) );
    This = Avg( [Product].[Color].[All].Children,
                [Measures].CurrentMember );
End Scope;
```

Detecting members on the same branch

So far, we've covered cases when there is a need to isolate a single member in the hierarchy, whether it is a root member or any other member in the hierarchy. This recipe deals with detecting the ascendants or descendants of a member in a hierarchy. As a matter of fact, the detection does not need to go all the way to the top level or to the leaf level; it can detect only a certain cascading branch in a hierarchy.

Multilevels are often found in user hierarchies. For a certain member, we might need to apply certain calculations to its ascendants only, or its descendants only, or to only part of a cascading branch in the hierarchy. Let's illustrate this with a couple of examples.

Suppose we want to analyze dates. There's a concept of the current date, but since that date is usually found in a multilevel user hierarchy, we can also talk about the current month, current quarter, current year, and so forth. They are all ascendants of the current date member. For the month of April 2013, we might need to detect all its parents, Q2 CY 2013, H1 CY 2013, and CY 2013, and apply some special calculations to them.

Another example is the `Customer Geography` user hierarchy. There, we can detect whether a particular customer is living in a particular city, or if that city is in the state or country in the context. In other words, we can test preceding and following levels, as long as there are levels to be detected in each direction.

In this recipe, we are going to use the `Product Categories` user hierarchy and a particular member `Touring Bikes` on the Subcategory level. The reason we picked the subcategory level is because it is a middle level in the `Product Categories` user hierarchy. We want to demonstrate how to check whether a particular member in a middle level is on the selected drill-up/down part in the hierarchy.

Getting ready

Open the SQL Server Data Tools (SSDT) and then open the Adventure Works DW 2016 solution. Double-click on the Adventure Works cube and go to the **Calculations** tab. Choose **Script View**. Position the cursor at the end of the script.

We'll base the example for this recipe on providing a special calculation for `Touring Bikes`.

How to do it...

Follow these steps to detect members on the same branch:

1. Add the `Scope()` statement.
2. Specify that you want **Touring Bikes** and all of their descendants included in this scope:

```
Scope( Descendants(
    [Product].[Product Categories].[Subcategory].&[3], ,
    SELF_AND_AFTER
)
);
[Measures].[Internet Sales Amount] = 1;
End Scope;
```

3. Save and deploy the script (or just press the **Deploy MDX Script** icon if you're using BIDS Helper).
4. Go to the **Cube Browser** tab and optionally reconnect.
5. Click on the icon **Analyze in Excel** on top, and choose the **Adventure Works** perspective. When the pivot table is open, select the measure **Internet Sales Amount** from the field list.
6. Select the **[Product Categories]** user hierarchy from the field list, and expand it until you see all the touring bikes, as displayed in the following screenshot:

A	B
Row Labels	Internet Sales Amount
Accessories	\$700,759.96
Bikes	\$24,473,344.60
Mountain Bikes	\$9,952,759.56
Road Bikes	\$14,520,584.04
Touring Bikes	1
Touring-1000 Blue, 46	1
Touring-1000 Blue, 50	1
Touring-1000 Blue, 54	1
Touring-1000 Blue, 60	1
Touring-1000 Yellow, 46	1
Touring-1000 Yellow, 50	1
Touring-1000 Yellow, 54	1
Touring-1000 Yellow, 60	1
Touring-2000 Blue, 46	1
Touring-2000 Blue, 50	1
Touring-2000 Blue, 54	1
Touring-2000 Blue, 60	1
Touring-3000 Blue, 44	1
Touring-3000 Blue, 50	1
Touring-3000 Blue, 54	1
Touring-3000 Blue, 58	1
Touring-3000 Blue, 62	1
Touring-3000 Yellow, 44	1
Touring-3000 Yellow, 50	1
Touring-3000 Yellow, 54	1
Touring-3000 Yellow, 58	1
Touring-3000 Yellow, 62	1
Clothing	\$339,772.61
Grand Total	\$25,513,877.17

7. Verify that the result for all **Touring Bikes**, including their total, is **1**, as defined in the scope statement.
8. Bring another measure, for example, **Reseller Sales Amount** and verify that this measure remains intact; the scope is not affecting it.

How it works...

The `Scope()` statement is used to isolate a particular part of the cube, also called the subcube, in order to provide a special calculation for that space. It starts with the `Scope` keyword followed by the subcube and ends with the `End Scope` phrase. Everything inside is valid only for that particular scope.

In this case, we formed the subcube by using the `Descendants()` function to get all the descendants of the member **Touring Bikes** and the member **Touring Bikes** itself. There are various ways that we can collect members on a particular branch using the `Ascendants()` and `Descendants()` function. These ways will be covered in the later sections of this recipe.

Once we have set our subcube correctly, we can provide various assignments inside that scope. Here, we have specified that the value for the **Internet Sales Amount** measure is to be 1 for every cell in that subcube.

It is worth noticing that the **Touring Bikes** total is not calculated as an aggregate of its children. This is because we have used the flag `SELF_AND_AFTER` in the `Descendants()` function; therefore, the member representing that total was included in the scope.

Therefore, a constant value of 1 has been assigned to it, the same way it was assigned to its children. Consequently, the **Touring Bikes** member contributes with its own value, 1, as the **Touring Bikes** total.

If the `AFTER` flag had been used in the `Descendants()` function, the **Touring Bikes** member would have been left out of that scope. In that case, its value would be equal to the sum of its children, that is, 22. The aggregate value of 22 would be used as its contribution to the **Touring Bikes** total.

It is worth noting that regular measures roll up their children's values using aggregate functions (`Sum`, `Max`, `Min`, and others) that are specified in the measure property `AggregateFunction`. Calculated measures do not roll up. They are calculated by evaluating their expression for every single member, be it parent or child.

There's more...

The earlier example showed how to isolate a lower part of a hierarchy, a part following a particular member. In this section, we're going to show that the opposite is not so easy, but still possible.

In cases where we need to scope a part of the hierarchy above the current member, we might be tempted to do the obvious, to use the opposite MDX function, the `Ascendants()` function. However, that would result in an error because the subcube wouldn't be compact any more. The term *arbitrary shape* represents a subcube formed by two or more smaller subcubes of different granularity, something that is not allowed in the scopes. The solution is to break the bigger subcube into many smaller ones, so that each can be considered compact, with data of consistent granularity. More about which shapes are arbitrary and which are not can be found in the Appendix and on this site:

<http://tinyurl.com/ArbitraryShapes>.

Here's an example for the **Mountain Bikes** member in which we show how to set the value to 2 for all of its ancestors:

```
Scope( Ancestors(
    [Product].[Product Categories].[Subcategory].&[1],
    1
);
    [Measures].[Internet Sales Amount] = 2;
End Scope;

Scope( Ancestors(
    [Product].[Product Categories].[Subcategory].&[1],
    2
);
    [Measures].[Internet Sales Amount] = 2;
End Scope;
```

This is the result:

	A	B
1	Row Labels	Internet Sales Amount
2	⊕ Accessories	\$700,759.96
3	⊕ Bikes	2
4	⊕ Mountain Bikes	\$9,952,759.56
5	⊕ Road Bikes	\$14,520,584.04
6	⊕ Touring Bikes	1
7	Touring-1000 Blue, 46	1
8	Touring-1000 Blue, 50	1
9	Touring-1000 Blue, 54	1
10	Touring-1000 Blue, 60	1
11	Touring-1000 Yellow, 46	1
12	Touring-1000 Yellow, 50	1
13	Touring-1000 Yellow, 54	1
14	Touring-1000 Yellow, 60	1
15	Touring-2000 Blue, 46	1
16	Touring-2000 Blue, 50	1
17	Touring-2000 Blue, 54	1
18	Touring-2000 Blue, 60	1
19	Touring-3000 Blue, 44	1
20	Touring-3000 Blue, 50	1
21	Touring-3000 Blue, 54	1
22	Touring-3000 Blue, 58	1
23	Touring-3000 Blue, 62	1
24	Touring-3000 Yellow, 44	1
25	Touring-3000 Yellow, 50	1
26	Touring-3000 Yellow, 54	1
27	Touring-3000 Yellow, 58	1
28	Touring-3000 Yellow, 62	1
29	⊕ Clothing	\$339,772.61
30	Grand Total	2

The value **1** for **Touring Bikes** and its children is from the previous scope script. But notice the value **2** in the **Bikes Total** row. The same value can be seen in the **Grand Total** row, highlighted in the bottom of the image. Both the **Bikes Total** and **Grand Total** are the ancestors of member **Mountain Bikes**. The calculation worked as expected.

The query-based alternative

These two scope-based calculations can easily be turned into query-based calculations in cases where the calculation is not required to persist in all queries.

Here's the query that returns exactly the same thing as those scope statements we've covered so far, one in the initial example and two in the *There's more* section:

```
WITH
MEMBER [Measures].[Branch detected on member or below] AS
    iif( IsAncestor(
        [Product].[Product Categories].[Subcategory].&[3],
        [Product].[Product Categories].CurrentMember
    )
    OR
    [Product].[Product Categories].[Subcategory].&[3] Is
    [Product].[Product Categories].CurrentMember,
    True,
    null
)
MEMBER [Measures].[Branch detected on member or above] AS
    iif( Intersect(
        Ascendants(
            [Product].[Product Categories].[Subcategory].&[3]
        ),
        [Product].[Product Categories].CurrentMember
    ).Count > 0,
    True,
    null
)
SELECT
    { [Measures].[Branch detected on member or above],
      [Measures].[Branch detected on member or below] } ON 0,
NON EMPTY
    { [Product].[Product Categories].AllMembers } ON 1
FROM
    [Adventure Works]
```

The first calculated measure detects descendants of the current member. It uses the `IsAncestor()` function and detects whether the current member is beneath the selected member in the hierarchy. That function returns `False` for the member itself. Therefore, we have to incorporate additional logic in the form of testing for the presence of a particular member, which is explained in the first recipe of this chapter, *Detecting a particular member in a hierarchy*.

The second calculation detects the descendants of the current member. It uses the `Ascendants()` function to get all the members above and including the selected one. When that set is obtained, we test whether the current member is in the set of descendants. The test is performed using the `Intersect()` and `Count` functions.

Here's another query-based alternative, this time using a `CELL CALCULATION`:

```
WITH
  CELL CALCULATION [Touring Bikes]
  FOR '( [Measures].[Internet Sales Amount],
         Descendants( [Product].[Product Categories]
                       .[Subcategory].&[3], ,
                       SELF_AND_AFTER
                     )
       )
  AS 1
  SELECT
    { [Measures].[Internet Sales Amount] } ON 0,
    Descendants(
      [Product].[Product Categories].[Subcategory].&[3], ,
      SELF_AND_AFTER
    ) ON 1
  FROM
    [Adventure Works]
```

As you can see, a cell calculation does the same thing a `Scope()` statement does in MDX script—it provides an expression for a particular subcube. A `CELL CALCULATION` is one of the three elements that can be defined using the `WITH` keyword in an MDX query. Here's more information about it: <http://tinyurl.com/CellCalculations>.

Now, what happens if we want to exclude the selected member in those calculations?

The first calculation in the query we started this section with is easy. We simply have to omit the part next to the `OR` statement, keeping only the `IsAncestor()` part of the expression.

The second calculation is a bit more complex but it can also be done. All we have to do is extract the selected member from the set of descendants. This can be done relatively easily using the `Except()` function:

```
Except(
    Ascendants(
        [Product].[Product Categories].[Subcategory].&[3]
    ),
    [Product].[Product Categories].CurrentMember )
```

Other parts of the calculation remain the same.

In the query with the `CELL CALCULATION`, we have to change the `SELF_AND_AFTER` flag into the `AFTER` flag. We don't have to do the same for the set on rows, only in cell calculation, where this behavior is defined.

Children() will return empty sets when out of boundaries

Under certain conditions, some MDX functions generate empty sets as their result; others always return a non-empty set. It is therefore good to know which one is preferred in which scenario, because an empty set will result in an empty value and this may cause problems in some calculations.

The `Descendants()` function will almost always return a result. If there are no children under the member or the set defined as the first argument, then it will return the member or the set itself. On the other hand, the `Children()` function will return an empty set when applied to members on the leaf level.

The `Ascendants()` function behaves pretty much the same as the `Descendants()` function. If the specified member is at the top level, it will return the member itself. On the other hand, the `Parent` function when applied to the root member or a top-level calculated member returns an empty set. The same is true for the `Ancestors()` and the `Ancestor()` functions. When out of boundaries, they return an empty set as well.

Based on how you want your calculation to react, you should use the function that is most appropriate in a particular case.

Various options of the Descendants() function

The following link provides more information about the `Descendants()` function and how to use its arguments: <http://tinyurl.com/MDXDescendants>.

- Chapter 9, *Metadata-driven Calculations*

Finding related members in the same dimension

The dimensionality of a cube equals the number of hierarchies used in it. This encompasses all the user and attribute hierarchies, including a special hierarchy `Measures`, visible or not, as long as they are enabled. A cube with 10 dimensions, each having 10 attribute hierarchies, is a 101D object! Comparing that to any 3D objects in your environment, such as a Rubik's cube, you will immediately be amazed by the space a typical SSAS cube forms. The number of coordinates, or shall we say cells, in that space is simply beyond our imagination.

Fortunately, a great deal of that space is empty and the SSAS engine has ways to optimize that. It even exposes some of the optimization features to us through several MDX functions we can use when needed.

In this recipe, we are going to look at two hierarchies, `Color` and `Subcategory`, and find the number of available colors in each of the product subcategories. Although these two hierarchies are from the same `Product` dimension, the number of all the possible combinations of `Color` and `Subcategory` can still be enormous. Our goal is to find only the existing colors for each product subcategory.

Because of the enormous possible combinations of the hierarchies, from the same dimension or not, in a typical cube, we should always pay attention to optimization. In this recipe, we will cover a type of optimization that is related to combining hierarchies from the same dimension. In the next recipe, we will cover a type of optimization that is related to optimizing the combination of hierarchies from different dimensions.

Getting ready

Start SQL Server Management Studio and connect to your SSAS 2016 instance. Click on the **New Query** button and check that the target database is Adventure Works DW 2016.

Here's the query we'll start from:

```
SELECT
    { [Measures].[Internet Order Count] } ON 0,
    { [Product].[Subcategory].[Subcategory].Members *
      [Product].[Color].[Color].Members } ON 1
FROM
    [Adventure Works]
```

Once executed, the query returns all product subcategories cross-joined with product colors. Scroll down your result and compare it with the following screenshot:

		Internet Order Count
Road Bikes	Black	3,030
Road Bikes	Red	2,719
Road Bikes	Yellow	2,319
Road Frames	Black	(null)
Road Frames	Red	(null)
Road Frames	Yellow	(null)
Saddles	NA	(null)
Shorts	Black	1,019
Socks	White	568
Tights	Black	(null)
Tires and Tubes	NA	9,867
Touring Bikes	Blue	1,283
Touring Bikes	Yellow	884
Touring Frames	Blue	(null)
Touring Frames	Yellow	(null)
Vests	Blue	562
Wheels	Black	(null)

It is worth noticing that the result is not a Cartesian product of those two hierarchies. With over 30 different subcategories and 10 different colors in the Product dimension, a Cartesian product of these two hierarchies would return over 300 different combinations. The engine, however, has automatically reduced the two-dimensional set on rows to a set of existing combinations only. The reason why this was possible follows.

The two hierarchies `Color` and `Subcategory` belong to the same dimension `Product`. A dimension originates from the underlying table (or a set of them in a snowflake model). The columns on the underlying table become attribute hierarchies. There are only a finite number of various combinations of attributes, and that number is almost always less than a Cartesian product of those attributes. The engine merely has to read that table and return the set of distinct combinations of the attributes for a particular case.

Of course, that is not exactly how it is done, but you get a good idea of how the multidimensional space is automatically shrunk whenever possible.

Notice also that this is not a result of the `NON EMPTY` keyword on rows because we didn't put it there. That keyword does something else: it removes empty fact rows. As seen in the preceding screenshot, we have many rows with the value of null in them. We deliberately didn't use that keyword to show the difference between what is known as the `auto-exists` algorithm and what `NON EMPTY` does.

Now, let's get back to the solution and see how to get the number of colors per subcategory without displaying colors on the query axis.

How to do it...

Follow these steps to find related members in the same dimension:

1. Add the `WITH` part of the query.
2. Create a new calculated measure and name it `Number of colors`.
3. Remove the set with `[Product].[Color]` hierarchy from rows and move it inside the definition of the new measure. Only product subcategories should remain on rows.
4. Use the `EXISTING` function before the set of color members and wrap everything in the `Count()` function.
5. Add this calculated measure on axis 0, next to the existing measure.

6. Execute the query, which should look like this:

```
WITH
  MEMBER [Measures].[Number of colors] AS
    Count( EXISTING [Product].[Color].[Color].Members )
  SELECT
    { [Measures].[Internet Order Count],
      [Measures].[Number of colors] } ON 0,
    { [Product].[Subcategory].[Subcategory].Members
      } ON 1
  FROM
    [Adventure Works]
```

7. Scroll down to the end and verify that the result matches the following screenshot:

	Internet Order Count	Number of colors
Road Bikes	8,068	3
Road Frames	(null)	3
Saddles	(null)	1
Shorts	1,019	1
Socks	568	1
Tights	(null)	1
Tires and Tubes	9,867	1
Touring Bikes	2,167	2
Touring Frames	(null)	2
Vests	562	1
Wheels	(null)	1

How it works...

By default, sets are evaluated within the context of the cube, not within the current context. The EXISTING keyword forces the succeeding set to be evaluated in the current context. Without it, the current context would be ignored and for each subcategory we would get 10 colors, which are all the distinct colors on the Product dimension table.

After that, we apply the Count () function in order to get the dynamic count of colors, a value calculated for each row separately.

There's more...

There might be situations when you'll have multiple hierarchies of the same dimension in the context, but you'll only want some of them to have an impact on the selected set. In other words, there could have been sizes from the [Size] attribute next to product Subcategories on rows. If you use the EXISTING keyword on colors, you'll get the number of colors for each combination of the subcategory and the site. In cases where you need your calculation to ignore the current size member and get the number of colors per subcategory only, you will have to take another approach. If you're wondering why you would do such a thing, just imagine you need an indicator which gives you a percentage of the color per size and subcategory. That indicator would have an unusual expression in its denominator and the usual expression in its numerator.

OK, so what's the solution in this case and how do we make such a calculation?

The Exists () function comes to the rescue. In fact, that function does the same thing as the EXISTING keyword, but it requires a second argument in which we need to specify the context for the evaluation.

Here's an example query:

```
WITH
MEMBER [Measures].[Number of colors] AS
    Count( EXISTING [Product].[Color].[Color].Members )
MEMBER [Measures].[Number of colors per subcategory] AS
    Count( Exists( [Product].[Color].[Color].Members,
                  { [Product].[Subcategory].CurrentMember } ) )
)
SELECT
    { [Measures].[Internet Order Count],
      [Measures].[Number of colors],
      [Measures].[Number of colors per subcategory] } ON 0,
    { [Product].[Subcategory].[Subcategory].Members *
      [Product].[Size Range].[Size Range].Members } ON 1
FROM
    [Adventure Works]
```

Once run, this query returns two different color-count measures. The first is unique to each row; the second changes by subcategory only. Their ratio, not present but easily obtainable in the query, would return the percentage of color coverage. For example, in the following screenshot, it is obvious that there's only 33 percent color coverage for 38-40 CM Road Bikes, which may or may not be a signal to fill the store with additional colors for that subcategory. The important thing is that we were able to control the context and fine-tune it:

		Internet Order Count	Number of colors	Number of colors per subcategory
Pedals	NA	(null)	1	1
Pumps	NA	(null)	1	1
Road Bikes	38-40 CM	782	1	3
Road Bikes	42-46 CM	2,235	3	3
Road Bikes	48-52 CM	3,091	3	3
Road Bikes	54-58 CM	1,355	2	3
Road Bikes	60-62 CM	605	2	3
Road Frames	38-40 CM	(null)	1	3
Road Frames	42-46 CM	(null)	3	3
Road Frames	48-52 CM	(null)	3	3
Road Frames	54-58 CM	(null)	2	3
Road Frames	60-62 CM	(null)	2	3
Saddles	NA	(null)	1	1
Shorts	L	363	1	1

We can also turn it the other way around. The `EXISTING` keyword is in fact a shortcut, a shorter version of the `Exists()` function which says *take everything available as the second argument, don't force me to specify everything*. The `EXISTING` keyword is therefore a more flexible, generic variant which handles any context. When we want to take control over the context, we can step back to the `Exists()` function.

Tips and trick related to the EXISTING keyword

Another way of specifying the EXISTING keyword is by using the MDX function with the same name. The following expression using the Existing() function is the same as using the EXISTING keyword:

```
Existing( [Product].[Color].[Color].Members )
```

This may come in handy with cross-joins because the cross-join operator * has precedence over the EXISTING keyword. In the following pseudo-expression, the EXISTING keyword will be applied to the cross-joined set, and not the first set in the cross-join:

```
EXISTING set_expression1 * set_expression2
```

In order to apply EXISTING to the first set, wrap the first set including the EXISTING keyword in curly brackets, like this:

```
{ EXISTING set_expression1 } * set_expression2
```

We can also use the alternative Existing() function for the first set:

```
Existing( set_expression1 ) * set_expression2
```

Filter() versus Exists(), Existing(), and EXISTING

Never iterate on a set unless you really have to, because iteration is slow. Use specialized functions which operate on sets whenever possible. They are designed to leverage the internal structures and therefore operate much faster.

A Filter() function filters a specified set based on a search condition by iterating through each tuple in the specified set. This recipe hopefully showed there's no need to filter a set of members if that set is related to the current context, in other words, that it belongs to the same dimension, as explained in the introduction. Exists(), Existing(), or the EXISTING keyword are better choices because they are functions optimized to work in block mode.

A friendly warning

After reading the subsequent recipe about finding related members on a different dimension, you might be tempted to use the technique described in that recipe here as well. The idea of not having to memorize each approach separately is an attractive one. A unique, all-purpose way of finding a related member no matter where it is.

You should know that, although it would work, it would be an inefficient solution. The performance could suffer greatly.

The reason for this lies in the fact that if you stick with the solution presented in this recipe, the SSAS engine will be able to perform a fast auto-exist operation on a single dimension table. The solution presented in the subsequent chapter relies on a join between the dimension table and the fact table. Now, all of a sudden, the engine has an N times larger table to scan. That could be a very costly operation if the engine is not optimized to reduce the unnecessary complexity involved here. Such complexity is not needed at all in this scenario! Therefore, try to make a difference in your mind between finding related members in the same dimension and finding related members in another dimension, and approach each case using a different, but appropriate, technique.

The difference between this recipe and the next recipe is finding the related members in the same dimension versus related members from two different dimensions. The solution presented in this recipe for finding the related members in the same dimension allows SSAS engine to perform a fast auto-exist operation on a single dimension table. The solution presented in the next recipe relies on a slow join between a dimension table and a fact table, forcing the engine to scan a data set that is N times larger than the dimension table itself.

The procedure mentioned earlier serves the purpose of illustrating the concept; it doesn't necessarily represent the actual implementation in the engine.

- Other aspects of the EXISTING keyword are covered in the *Optimizing MDX query using the NonEmpty() function* recipe in Chapter 1, *Elementary MDX Techniques*. You may gain a better understanding of that keyword by reading that recipe.
- Also, read the *Finding related members in another dimension* recipe in order to understand the difference between finding related members in the same dimension and in different dimensions.

Finding related members in another dimension

As mentioned in the introduction of the previous recipe, *Finding related members in the same dimension*, this recipe deals with a slightly different scenario. It explains how to find the related members from two or more different dimensions.

Before we start, please keep in mind that when we say a **dimension**, we mean any hierarchy in that dimension from now on.

Dimensions, unlike hierarchies of the same dimension, are unrelated and therefore independent objects. Without a third table in the form of a third fact table, they are unrelated, at least in the dimensional modeling sense. When a fact table is inserted among them, the many-to-many relationship comes into existence.

There are two different types of combination we can make with the dimensions. One type is the Cartesian product because they are unrelated. It is obtained by cross-joining members in both dimensions. In relational terms, that would represent the `CROSSJOIN` of two tables. Since those tables are two independent objects, we get a real Cartesian product.

The other combination is a combination of a fact table and an intermediate table for two or more dimensions. This fact table can serve as a filter. We can use it to get members in the second dimension, members which have associated records, or non-empty values in the fact table for the valid members in the first dimension. A typical example would be *find me products that are available on a particular territory, are bought by a particular customer, or are shipped on a particular date*. The first dimension in this case contains the territory, customers, and dates respectively; the second one is the product dimension; the fact table or the measure group could be the sales orders or any measure group of interest to us.

The previous requirement example can be accomplished by cube design in SSAS alone. All we have to do is position the selected member or more of them in the slicer, turn the `NON EMPTY` keyword on rows, and provide a set of members from the other dimension on rows and a measure of our interest on columns. The result would meet our requirement. This type of operation is natural for any SSAS client, and it is available for ad hoc analysis.

However, as we've learned quite a few times throughout this book, there are always situations when we need to have a control over certain calculations, and the controlled calculations might need to get not all but only the related members, in another dimension. Is there a way to support this? Yes, this recipe shows how.

In this recipe, we are going to use the `Reseller` dimension and we are going to find out how many subcategories each of the top 100 resellers is ordering.

The `Reseller` and `Subcategory` are two hierarchies from two different dimensions. Our goal is to find their combinations that have associated rows in the fact table of the specified measure group `Reseller Orders`.

Getting ready

Start SQL Server Management Studio and connect to your SSAS 2016 instance. Click on the **New Query** button and check that the target database is Adventure Works DW 2016.

Here's the query we'll start from:

```
SELECT
    { [Measures].[Reseller Order Count] } ON 0,
    { TopCount( [Reseller].[Reseller].[Reseller].Members,
        100,
        [Measures].[Reseller Order Count] ) *
        [Product].[Subcategory].[Subcategory].Members } ON 1
FROM
    [Adventure Works]
```

Once executed, the query returns the top 100 resellers based on their ordering frequency combined with product subcategories. The `NON EMPTY` keyword is omitted intentionally in order to show a Cartesian product in action.

Combining 100 customers with 37 subcategories makes 3,700 rows. The result is a Cartesian product of `Reseller` and `Subcategory`, which are from two different dimensions.

Scroll down to the last row, highlight it, and check the status bar of SSMS. That extra row, the 3,701st, is the column header row.

It is easy to notice that many combinations of `Reseller` and `Subcategory` produce a `NUL` reseller order. We have two goals in this recipe. The first is to show `Reseller` only on the rows. The second is to count the number of `Subcategory` for each `Reseller` with a condition that the combination actually has associated rows in the reseller order fact table.

The key part of the solution is to find combinations from two different dimensions that have associated rows in the fact table of the specified measure group:

		Reseller Order Count
Big-Time Bike Store	Road Bikes	8
Big-Time Bike Store	Road Frames	8
Big-Time Bike Store	Saddles	2
Big-Time Bike Store	Shorts	(null)
Big-Time Bike Store	Socks	1
Big-Time Bike Store	Tights	(null)
Big-Time Bike Store	Tires and Tubes	(null)
Big-Time Bike Store	Touring Bikes	(null)
Big-Time Bike Store	Touring Frames	(null)
Big-Time Bike Store	Vests	(null)
Big-Time Bike Store	Wheels	3

How to do it...

Follow these steps to find related members from Reseller and Subcategory through the fact table of the measure group Reseller Orders:

1. Add the WITH part of the query.
2. Create a new calculated measure and name it Count of SubCategory - Exists.
3. Remove the set with the [Product].[Subcategory] hierarchy from rows and move it inside the definition of the new measure. Only the resellers should remain on rows.
4. Use the variant of the Exists() function which has the third argument, the measure group name. In this case, you should use the measure group containing the measure Reseller Order Count. The name of that measure group is Reseller Orders.
5. Finally, wrap everything with the Count() function.
6. Add this calculated measure on axis 0, next to the existing measure.

7. Execute the query, which should look like this:

```
WITH
MEMBER [Measures].[Count of SubCategory - Exists] AS
    Count( Exists(
        [Product].[Subcategory].[Subcategory].Members, ,
        'Reseller Orders' ) )
SELECT
    { [Measures].[Reseller Order Count],
      [Measures].[Count of SubCategory - Exists] } ON 0,
    { TopCount( [Reseller].[Reseller].[Reseller].Members,
      100,
      [Measures].[Reseller Order Count] ) *
      [Product].[Subcategory].[Subcategory].Members } ON 1
FROM
    [Adventure Works]
```

8. Verify that the result matches the following screenshot:

	Reseller Order Count	Count of SubCategory - Exists
Advanced Bike Components	12	22
Area Bike Accessories	12	19
Basic Sports Equipment	12	18
Better Bike Shop	12	21
Bike Dealers Association	12	22
Bike Goods	12	8
Brakes and Gears	12	13
Brightwork Company	12	17

How it works...

To find the related members from two different dimensions through a fact table, we used the `Exists()` function. The `Exists()` function has three variants, as shown:

```
Exists( Set_Expression1, Set_Expression2)
Exists( Set_Expression1, Set_Expression2, MeasureGroupName )
Exists( Set_Expression1, , MeasureGroupName )
```

The first variant without the third argument `MeasureGroupName` is useful for intersecting related attributes from the same dimension, as shown in the previous recipe, *Finding related members in the same dimension*. The second variant with the third argument `MeasureGroupName` is ideal for combining dimensions across a fact table. In SSAS, a measure group represents a fact table.

The third variant omits the second argument for a set expression. What this variant does is instruct the engine to return distinct members from the first set that have valid combinations with the current member in context, that is, the combinations have associated rows in the fact table of the specified measure group.

In our example, we have used the third variant, omitting the second set argument. The current member in context is every reseller on rows. This query context is established in the evaluation phase of the query. There's no need to use the current member as the second set; that member will be there implicitly.

Once we get a set of distinct members from the `Subcategory` hierarchy, all we have to do is count them using the `Count()` function.

There's more...

The alternative, although not exactly the same solution, would be to use the `NonEmpty()` function. Here's the query which, when run, shows that both count measures return the same results for each reseller:

```
WITH
MEMBER [Measures].[Count of SubCategory - Exists] AS
    Count(Exists(
        [Product].[Subcategory].[Subcategory].Members,
        'Reseller Orders'))
MEMBER [Measures].[Count of SubCategory - NonEmpty] AS
    Count(NonEmpty(
        [Product].[Subcategory].[Subcategory].Members,
        { [Measures].[Reseller Order Count] } ))
SELECT
    { [Measures].[Reseller Order Count],
        [Measures].[Count of SubCategory - Exists],
        [Measures].[Count of SubCategory - NonEmpty] } ON 0,
    { TopCount([Reseller].[Reseller].[Reseller].Members,
        100,
        [Measures].[Reseller Order Count]
    ) } ON 1
FROM
    [Adventure Works]
```

Since we've given a hint that this alternative of using `NonEmpty()` function is not exactly the same as the solution using the `Exists()`, now's the time to shed more light upon that.

The difference between the third variant of the `Exists()` function and the `NonEmpty()` function is subtle. They differ only on measures for which the `NullProcessing` property is set to `Preserve`. `NonEmpty()` is a more destructive function in this case, because it ignores fact records with nulls while `Exists()` preserves them. In cases where the measure's `NullProcessing` property is set to `Preserve`, we can have two different counts and use the one that best meets our reporting requirements. The other subtle difference is that the `Exists()` function ignores the MDX script and simply does a storage engine query. For example, if the MDX script nulls out a measure, the `Exists()` function will still return values.

The queries in this recipe so far have illustrated the concept behind the `Exists()` and `NonEmpty()` functions. These functions can be used to isolate related members on other dimensions. However, from the performance perspective, they are not great when you need to count members on other dimensions because the `count-exists` and the `count-nonempty` combinations are not optimized to run in block mode. The `sum-iif` combination, on the other hand, is optimized to run in block mode. Therefore, whenever you need to do something more than simply isolate related members on other dimensions (such as counting and so on), consider using a combination of functions that you know run in block mode.

Here's the query that outperforms the two queries shown so far in this recipe:

```
WITH
MEMBER [Measures].[Count of SubCategory - SumIIF] AS
    Sum( [Product].[Subcategory].[Subcategory].MEMBERS,
        iif( IsEmpty( [Measures].[Reseller Order Count] ),
            null,
            1 )
    )
SELECT
    { [Measures].[Count of SubCategory - SumIIF] } ON 0,
    { TopCount( [Reseller].[Reseller].[Reseller].MEMBERS,
        100,
        [Measures].[Reseller Order Count] ) *
        [Product].[Subcategory].[Subcategory].MEMBERS } ON 1
FROM
    [Adventure Works]
```

Leaf and non-leaf calculations

The examples in this and the previous recipe are somewhat complex from a technical perspective, but they are perfectly valid in many reporting requirements. From an analytical perspective, it is often required to get the count of existing members on a non-leaf level, such as at the subcategory level in our example.

When it's required to get the count of members on a leaf level, designing a distinct count measure using the dimension key in the fact table might be a better option. It will work by the cube design in SSAS; there is no code maintenance and it's much faster than its MDX counterpart. Therefore, look for a by-design solution whenever possible; don't assume that things should be handled in MDX just because this recipe indicated as such. *Chapter 8, When MDX Is Not Enough* deals with that in more detail.

When it is required to get the count on a non-leaf attribute, that's the time when MDX calculations and relations between hierarchies and dimensions come into play as valid solutions. Because either you are going to include that higher granularity attribute in your fact table (not likely, especially on large fact tables) and then build a distinct count measure from it, or you can build a new measure group at the non-leaf grain, or you will look for an MDX alternative like we did in this example and the one in the previous chapter. Additionally, the non-leaf levels will typically, although not always, have much lower cardinality than the leaf level, which means that MDX calculations will perform significantly better than they would on a leaf level.

This section serves the purpose of a reminder when it comes to the choice between cube design and MDX calculations. Knowing the pros and cons, you should be well on your way to making the right decision.

- Other aspects of the `NonEmpty()` function are covered in the *Optimizing MDX queries using the NonEmpty() function* recipe in Chapter 1, *Elementary MDX Techniques*. You may gain a better understanding of that function by reading that recipe.
- Also, read the *Finding related members in the same dimension* recipe in order to understand the difference between finding related members in the same dimension and in different dimensions.

Calculating various percentages

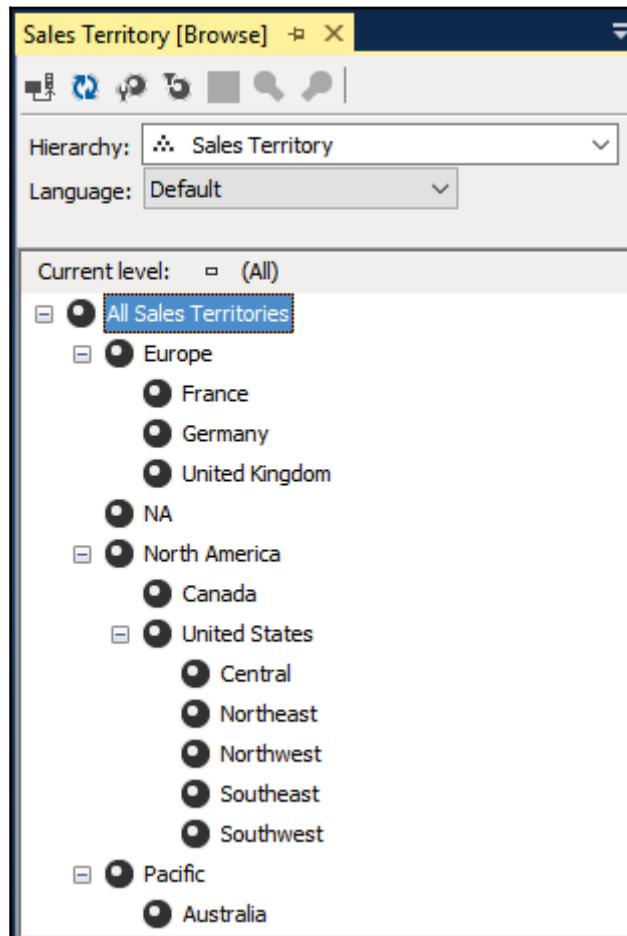

This recipe and the next two recipes show how to calculate relative percentages, averages, and ranks. We are starting with percentages in this recipe.

Having a ratio of a current member's value over their parent's value is an often-required calculation. It's a form of normalizing the hard-to-grasp values in the table. When the individual amounts become percentages, it immediately becomes clear where the good or bad values are.

There are many kinds of percentages or shares, but we'll take the typical three and present them in this recipe. These are: percentage of the parent's value, percentage of the level's total, and percentage of the hierarchy's total.

This recipe will show how to calculate them using the ragged `Sales Territory` hierarchy of the `Sales Territory` dimension. Unlike a balanced (or standard) hierarchy, whose branches all have the same level (or depth) with each member's parent being at the level immediately above the member, a ragged (or unbalanced) hierarchy is a hierarchy whose branches can have inconsistent depths. A typical example of a ragged hierarchy is an organization chart. The levels within the organizational structure are unbalanced, with some branches in the hierarchy having more levels than others.

In the Adventure Works cube, the **Sales Territory** hierarchy is a ragged hierarchy. This can be seen by browsing the **Sales Territory** hierarchy in SQL Server Management Studio, as shown in the following screenshot. The member **United States** is the only country in that hierarchy which has children, the regions. No other country in that hierarchy has them. This has created inconsistent depths in the hierarchy:

So, let's start!

Getting ready

Start SQL Server Management Studio and connect to your SSAS 2016 instance. Click on the **New Query** button and check that the target database is Adventure Works DW 2016.

Here's the query we'll start from:

```
WITH
  MEMBER [Measures].[Level] AS
    [Sales Territory].[Sales Territory]
      .CurrentMember.Level.Ordinal
SELECT
  { [Measures].[Level],
    [Measures].[Reseller Sales Amount] } ON 0,
  { [Sales Territory].[Sales Territory].AllMembers } ON 1
FROM
  [Adventure Works]
```

Once executed, the query returns the hierarchized territories in rows:

	Level	Reseller Sales Amount
All Sales Territories	0	\$80,450,596.98
Europe	1	\$10,870,534.80
France	2	\$4,607,537.94
Germany	2	\$1,983,988.04
United Kingdom	2	\$4,279,008.83
NA	1	(null)
North America	1	\$67,985,726.81
Canada	2	\$14,377,925.60
United States	2	\$53,607,801.21
Central	3	\$7,906,008.18
Northeast	3	\$6,932,842.01
Northwest	3	\$12,435,076.00
Southeast	3	\$7,867,416.23
Southwest	3	\$18,466,458.79
Pacific	1	\$1,594,335.38
Australia	2	\$1,594,335.38

In the columns, we have a little helper, the level ordinal displayed in the form of a measure. This level ordinal number helps us to see how the members are arranged and ordered in a hierarchy, with the **All Sales Territories** at the top, followed by the level 1 members and their children at level 2. We can also observe that only level 2 member **United States** has children at level 3.

Now we are ready to calculate three percentages for the **Reseller Sales Amount** measure. For each member in the rows, we will calculate its percentage of the parent's value, percentage of the level's total, and percentage of the hierarchy's total.

How to do it...

Follow these steps to calculate various percentages:

1. Create the first calculated measure for the percentage of the parent's value, name it `Parent %`, and provide the following definition for it:

```
MEMBER [Measures].[Parent %] AS
    iif( [Sales Territory].[Sales Territory].CurrentMember Is
        [Sales Territory].[Sales Territory].[All],
        1,
        [Measures].[Reseller Sales Amount] /
        (
            [Measures].[Reseller Sales Amount],
            [Sales Territory].[Sales Territory]
            .CurrentMember.Parent
        )
    ), FORMAT_STRING = 'Percent'
```

2. Create the second calculated measure for the percentage of the level's total value, name it `Level %`, and provide the following definition for it:

```
MEMBER [Measures].[Level %] AS
    [Measures].[Reseller Sales Amount] /
    Aggregate( [Sales Territory].[Sales Territory]
    .CurrentMember.Level.Members,
    [Measures].[Reseller Sales Amount] )
, FORMAT_STRING = 'Percent'
```

3. Create the third calculated measure for the percentage of the hierarchy's total value, name it `Hierarchy %`, and provide the following definition for it:

```
MEMBER [Measures].[Hierarchy %] AS  
    [Measures].[Reseller Sales Amount] /  
        ( [Sales Territory].[Sales Territory].[All],  
            [Measures].[Reseller Sales Amount] )  
    , FORMAT_STRING = 'Percent'
```

4. Include all three calculated measures in columns, execute the query, and verify that the result matches the following screenshot:

	Level	Reseller Sales Amount	Parent %	Level %	Hierarchy %
All Sales Territories	0	\$80,450,596.98	100.00%	100.00%	100.00%
Europe	1	\$10,870,534.80	13.51%	13.51%	13.51%
France	2	\$4,607,537.94	42.39%	5.73%	5.73%
Germany	2	\$1,983,988.04	18.25%	2.47%	2.47%
United Kingdom	2	\$4,279,008.83	39.36%	5.32%	5.32%
NA	1	(null)	(null)	(null)	(null)
North America	1	\$67,985,726.81	84.51%	84.51%	84.51%
Canada	2	\$14,377,925.60	21.15%	17.87%	17.87%
United States	2	\$53,607,801.21	78.85%	66.63%	66.63%
Central	3	\$7,906,008.18	14.75%	14.75%	9.83%
Northeast	3	\$6,932,842.01	12.93%	12.93%	8.62%
Northwest	3	\$12,435,076.00	23.20%	23.20%	15.46%
Southeast	3	\$7,867,416.23	14.68%	14.68%	9.78%
Southwest	3	\$18,466,458.79	34.45%	34.45%	22.95%
Pacific	1	\$1,594,335.38	1.98%	1.98%	1.98%
Australia	2	\$1,594,335.38	100.00%	1.98%	1.98%

How it works...

The Parent % measure returns the ratio of the current member's value over its parent's value. The parent's value is calculated relative to the current member, using the following tuple. In other words, the ratio returns a different value for each territory:

```
( [Measures].[Reseller Sales Amount],  
  [Sales Territory].[Sales Territory].CurrentMember.Parent )
```

One additional thing we have to take care of is handling the problem of the nonexisting parent of the root member. There's no such thing as the parent of the root member, meaning the calculation would result in an error for that cell. In order to take care of that, we've wrapped the calculation in an additional `iif()` statement. In it, we've provided the value of 1 (100% later) when the root member becomes the current member during the iteration phase on rows.

Similarly, we've defined the other two calculated measures.

For the Level % measures, we have used the following tuple to get the aggregated value of all the members at the same level as the current member as the denominator of the ratio:

```
Aggregate( [Sales Territory].[Sales Territory].CurrentMember.Level.Members,  
           [Measures].[Reseller Sales Amount] )
```

For the Hierarchy % measures, we have directly used the coordinate with the root member because the following tuple represents the total value of the hierarchy:

```
( [Sales Territory].[Sales Territory].[All],  
  [Measures].[Reseller Sales Amount] )
```

It is easy to notice that the Level % and the Hierarchy % measures return the same ratio at all levels except at level 3. This is because the aggregate of level 0, 1, or 2 would be practically the same as the value of the root member. If you add up the sales amount for all level 1 members, you would get \$80,450,596.98, which is the sales amount of the root member. It's the same with all level 2 members. However, the aggregated sales amount for the members on the third level is only \$53,607,801.21. This is because other level 2 members do not have children except the member **United States**.

There's more...

The examples in this recipe so far should give you a good start for percentage calculations. If you have reporting requirements for other types of percentage calculation, the following techniques might come in handy for you.

First, you can use the `SCOPE` statement within an MDX script if you need to calculate the percentage only for a part of your hierarchy.

Next, if you need only a single member in a denominator's tuple, use the `Ancestor()` function and provide the appropriate level. Otherwise, you will have to aggregate the set of members using the `Aggregate()` function, as shown in our example for the `Level %` calculation.

Finally, remember to take care of division by zero problems and problems related to nonexisting members in the hierarchy. One such example is the `Parent %` calculation, where we were detecting the root member because that's the only member in that hierarchy without a parent.

Use cases

The `Parent %` measure is the most requested and useful one. It is applicable in any hierarchy and gives an easy way to comprehend information about members in the hierarchy.

The `Hierarchy %` calculation is useful in the parent-child hierarchy to calculate the individual percentages of members scattered in various positions and levels of a parent-child hierarchy. In addition to that, this calculation is useful in user hierarchies when there is a need to calculate the percentage of members in lower levels with respect to the hierarchy's total, because the immediate parents and ancestors break the result into a series of 100% contributions.

Finally, the `Level %` measure is also useful in parent-child hierarchies.

Besides ragged hierarchies, the difference between the `Level %` and the `Hierarchy %` will manifest in other non-symmetrical structures; those are hierarchies with custom roll-ups and special scopes applied to them. Financial structures (dimensions) such as P&L and balance sheet are examples of these special types of hierarchies. In those scenarios, you might want to consider having both percentages.

The Hierarchy % calculated measure is performance-wise a better measure because it picks a coordinate in the cube directly. Moreover, that coordinate is the coordinate with the root member, something we can expect to have an aggregate for. Unless the situation really requires both of these measures, use the Hierarchy % measure only.

The alternative syntax for the root member

We have used the All level to get the root member in our example:

```
[Sales Territory].[Sales Territory].[All]
```

There is an alternative syntax for the root, and it is safe enough that we do not need to worry about possible errors. That definition is this:

```
Tail(  
    Ascendants(  
        [Sales Territory].[Sales Territory].CurrentMember  
    )  
).Item(0)
```

The expression basically says *take the last of the descendants of the current member and extract it from that set as a member.*

The descendants are always arranged in a hierarchy, which means that the last member in the set of descendants is the root we're after. Once we have that set, we can use the Tail() function to get the last member of that set. If we omit the second argument of the Tail() function, the value of 1 is implicitly applied.

The result of that function is still a set so we have to use the Item() function in order to convert that single-member set into as a member object. Only then can we use it in our tuple.

The case of the nonexisting [All] level

In SSAS, the [All] level is an optional, system-generated level. When the IsAggregatable property of a hierarchy is set to False, the hierarchy will have no (All) level. For example, in the Adventure Works cube, the Organizations hierarchy on the Organization dimension has the IsAggregatable property set to False. In this case, the following expression for the root member using the [All] level will return an empty object:

```
[Organization].[Organizations].[All]
```

However, the Tail-Ascendants expression in this case will correctly return the top level member:

```
Tail( Ascendants( [Organization].[Organizations].CurrentMember ) ).Item(0)
```

The percentage of leaf member values

The percentage on leaves is the fourth type of the percentage we can calculate. The reason we haven't is that an aggregate on leaves is almost always the same value as the value in the root member. If you have a different situation, use the following calculation:

```
MEMBER [Measures].[Leaves %] AS  
    [Measures].[Reseller Sales Amount] /  
    Aggregate(  
        Descendants( [Sales Territory].[Sales Territory]  
            .[All], ,  
            leaves ),  
        [Measures].[Reseller Sales Amount] )  
    , FORMAT_STRING = 'Percent'
```

This calculation takes all leaf members and then applies an aggregate of them in respect to the measure provided. Because of this, it might be significantly slower.

- The following recipes are part of the three-part series of recipes in this chapter dealing with the topic of relative calculations: *Calculating various averages* and *Calculating various ranks*. It is recommended that you read all of them in order to get a more thorough picture.

Calculating various averages

This is the second recipe in our series of relative calculations. In the previous recipe, *Calculating various percentages*, we created calculated measures for Parent %, Level %, Hierarchy %, and Leaves %. We used the ragged Sales Territory hierarchy of the Sales Territory dimension. There is a good introduction to ragged hierarchies in the previous recipe.

In this recipe, we will continue to use the ragged Sales Territory hierarchy of the Sales Territory dimension. We are going to show how to calculate the average among siblings, average in the level, average in the entire hierarchy, and average on leaves.

Getting ready

Start SQL Server Management Studio and connect to your SSAS 2016 instance. Click on the **New Query** button and check that the target database is Adventure Works DW 2016.

Here is the same initial query we used in the previous recipe for calculating various percentages:

```
WITH
MEMBER [Measures].[Level] AS
    [Sales Territory].[Sales Territory]
    .CurrentMember.Level.Ordinal
SELECT
    { [Measures].[Level],
        [Measures].[Reseller Sales Amount] } ON 0,
    { [Sales Territory].[Sales Territory].AllMembers } ON 1
FROM
    [Adventure Works]
```

Once executed, the query returns hierarchized territories on rows. Please refer back to the screenshot in the previous recipe.

On columns, we have a little helper, the level ordinal displayed in the form of a measure. This level ordinal number helps us to see how the members are arranged and ordered in a hierarchy, with the **All Sales Territories** at the top, followed by the level 1 members and their children at level 2. We can also observe that only the level 2 member **United States** has children at level 3.

In addition to the ordinal number for each level, we also have the main measure, the **Reseller Sales Amount** measure. That's the measure we'll use to calculate four different averages: **Siblings AVG**, **Level AVG**, **Hierarchy AVG**, and **Leaves AVG**.

How to do it...

Follow these steps to calculate these averages:

1. Create the first calculated measure for the average among the siblings, name it **Siblings AVG**, and provide the definition for it using the `Avg()` function and the `Siblings` function:

```
MEMBER [Measures].[Siblings AVG] AS  
    Avg( [Sales Territory].[Sales Territory]  
        .CurrentMember.Siblings,  
        [Measures].[Reseller Sales Amount] )
```

2. Create the second calculated measure for the average on level, name it **Level AVG**, and provide the definition for it using the `Avg()` function and the `Level` function:

```
MEMBER [Measures].[Level AVG] AS  
    Avg( [Sales Territory].[Sales Territory]  
        .CurrentMember.Level.Members,  
        [Measures].[Reseller Sales Amount] )
```

3. Create the third calculated measure for the average on hierarchy, name it **Hierarchy AVG**, and provide the definition for it using the `Avg()` function:

```
MEMBER [Measures].[Hierarchy AVG] AS  
    Avg( [Sales Territory].[Sales Territory].Members,  
        [Measures].[Reseller Sales Amount] )
```

4. Create the fourth calculated measure for the average on leaves, name it **Leaves AVG**, and provide the definition for it using the `Avg()` function and the version of the `Descendants()` function which returns leaves:

```
MEMBER [Measures].[Leaves AVG] AS  
    Avg( Descendants( [Sales Territory].[Sales Territory]  
        .[All], ,  
        Leaves ),  
        [Measures].[Reseller Sales Amount] )
```

5. Include all four calculated measures on columns, execute the query, and verify that the result matches the following screenshot:

	Level	Reseller Sales Amount	Siblings AVG	Level AVG	Hierarchy AVG	Leaves AVG
All Sales Territories	0	\$80,450,596.98	\$80,450,596.98	\$80,450,596.98	\$19,663,972.81	\$8,045,059.70
Europe	1	\$10,870,534.80	\$26,816,865.66	\$26,816,865.66	\$19,663,972.81	\$8,045,059.70
France	2	\$4,607,537.94	\$3,623,511.60	\$13,408,432.83	\$19,663,972.81	\$8,045,059.70
Germany	2	\$1,983,988.04	\$3,623,511.60	\$13,408,432.83	\$19,663,972.81	\$8,045,059.70
United Kingdom	2	\$4,279,008.83	\$3,623,511.60	\$13,408,432.83	\$19,663,972.81	\$8,045,059.70
NA	1	(null)	\$26,816,865.66	\$26,816,865.66	\$19,663,972.81	\$8,045,059.70
North America	1	\$67,985,726.81	\$26,816,865.66	\$26,816,865.66	\$19,663,972.81	\$8,045,059.70
Canada	2	\$14,377,925.60	\$33,992,863.40	\$13,408,432.83	\$19,663,972.81	\$8,045,059.70
United States	2	\$53,607,801.21	\$33,992,863.40	\$13,408,432.83	\$19,663,972.81	\$8,045,059.70
Central	3	\$7,906,008.18	\$10,721,560.24	\$10,721,560.24	\$19,663,972.81	\$8,045,059.70
Northeast	3	\$6,932,842.01	\$10,721,560.24	\$10,721,560.24	\$19,663,972.81	\$8,045,059.70
Northwest	3	\$12,435,076.00	\$10,721,560.24	\$10,721,560.24	\$19,663,972.81	\$8,045,059.70
Southeast	3	\$7,867,416.23	\$10,721,560.24	\$10,721,560.24	\$19,663,972.81	\$8,045,059.70
Southwest	3	\$18,466,458.79	\$10,721,560.24	\$10,721,560.24	\$19,663,972.81	\$8,045,059.70
Pacific	1	\$1,594,335.38	\$26,816,865.66	\$26,816,865.66	\$19,663,972.81	\$8,045,059.70
Australia	2	\$1,594,335.38	\$1,594,335.38	\$13,408,432.83	\$19,663,972.81	\$8,045,059.70

How it works...

The averages are calculated using the standard MDX function called `Avg()`. That function takes a set of members and calculates the average value of the measure provided as the second argument of that function throughout that set of members. The only thing we have to take care of is to provide a good set of members, the one we need the average to be calculated on.

The set of members for the average among siblings calculation is obtained using the `Siblings` function. The set of members for the average on level calculation is obtained using the `Level` function. The set of members for the average on hierarchy calculation is obtained using the `Members` function only, applied directly to the hierarchy, not an individual level. That construct returns all members in that hierarchy, starting from the root member and ending with all leaf members. Finally, the set of members for the average on leaves calculation is obtained by isolating the leaf members using the `Descendants()` function.

There's more...

Most of these average measures are not intended to be displayed in a grid as we've done here. They are more frequently used as a denominator in various ratios or other types of calculations. For example, it might be interesting to see the discrepancy of each value against one or more average values. That way, we can separate members performing below the average from those above the average, particularly if we apply additional conditional formatting to the foreground or the background colors of the cells.

The first two average calculations, `Siblings AVG` and `Level AVG`, are applicable to any hierarchy. The `Hierarchy AVG` and `Leaves AVG` measures are more applicable in parent-child hierarchies and other types of non-symmetrical hierarchies. The `Employee.Employees` hierarchy is another example where the calculation of the `Hierarchy AVG` and `Leaves AVG` measures makes perfect business sense.

The `Employee.Employees` hierarchy is a parent-child hierarchy. Employees are found on all levels in that hierarchy. It makes sense to calculate the average value for all employees, no matter which level they are found at, so that we can compare each employee's individual value against the average value of all employees. This is the calculation of `Hierarchy AVG`.

The same process can be restricted to employees that have no one underneath them in the corporate hierarchy, that is, employees which are located as leaves in that hierarchy. It makes sense to calculate their individual contribution against the average value of all such leaf employees. This way, we could notice and promote those above-average employees by hiring new ones as their subordinates. This is the calculation of `Leaves AVG`.

Preserving empty rows

The average is rarely an empty value. In other words, it's a dense type of calculation in general.

The consequence of making a dense calculation is that we need to identify the situations where it makes sense to set it to the `null` value.

Take a look at the screenshot with the results again and you'll notice there's a row with the `null` value for the `Reseller Sales Amount`, but the averages are not `null` themselves. That's what a dense calculation is.

We normally do not want the rows where the original measure is `null`. We generally tend to use the `NON EMPTY` keyword on axes in order to remove the entire empty rows. In this example, we've deliberately omitted that keyword in order to demonstrate this issue, but in a real situation, we would have applied it on rows.

The issue we have is that `NON EMPTY` works only when the complete row is empty. Any calculated measures that come from the dense calculations can spoil that.

In order to deal with this issue, we can wrap all calculations for averages in an outer `iif()` statement and detect an empty value for the original measure there. This way, we will be able to return `null` when the original measure is empty, and applying the `NON EMPTY` keyword on axes will remove the empty rows. As mentioned in many examples in this book, the `iif()` function is optimized to perform well when one of the branches is `null`. To detect an empty value for the original measure, we will use the `IsEmpty()` function.

Here's an example of how to correct previous calculations:

```
MEMBER [Measures].[Siblings AVG] AS
    iif( IsEmpty( [Measures].[Reseller Sales Amount] ),
        null,
        Avg( [Sales Territory].[Sales Territory]
            .CurrentMember.Siblings,
            [Measures].[Reseller Sales Amount]
        )
    )
```

We could do the same for the rest of the calculated measures, including the `Level` measure.

Other specifics of average calculations

The `Avg()` function returns the average value of non-empty cells only. If you want to create something like a rolling three-month average where some of the months may be empty, you will need to modify or adjust your calculation.

One way of doing this is to break the calculation in two so that the numerator calculates the sum of a set and the denominator calculates the count of members (or tuples in general) in that set. The `Count()` function counts empty cells by default. But you can always set its optional second flag to `INCLUDEEMPTY` to count all members in a set.

The other solution is to modify the second argument in the `Avg()` function so that the expression is never null, either by using the `CoalesceEmpty()` function or by using a dense calculated measure, which is never empty. The sum over count approach is the preferred approach because it preserves the format of measures.

Here, you can find more information about the MDX functions mentioned in this section and their specifics, including examples: <http://tinyurl.com/AvgInMDX> and <http://tinyurl.com/CountInMDX> and <http://tinyurl.com/CoalesceEmptyInMDX>.

The **Sum-Count** approach is also the best approach when you need the average on granularity, when you need an aggregation function to calculate the average sales amount, or similar. Notice there's no `Avg` aggregation function, only `Sum`, `Count`, `Max`, `Min`, `DistinctCount`, and those semi-aggregatable functions available only in the Enterprise version of SQL Server Analysis Services. In other words, the average aggregation is done by creating two regular measures, one that sums the value and another one that counts the rows, and then a calculated measure as their ratio.

You can always create various scope statements inside the MDX script, thereby breaking the complexity of the requested functionality into a subset of smaller, more compact calculations.

See also

- The following recipe is part of the three-part series of recipes in this chapter dealing with the topic of relative calculations: *Calculating various percentages* and *Calculating various ranks*. It is recommended that you read all of them in order to get a more thorough picture.
- Chapter 9, *Metadata-driven Calculations*.

Calculating various ranks

This is the final recipe in our series of relative calculations. In this recipe, we're going to show how to calculate the rank among siblings, the rank on a level, and the rank in the entire hierarchy. A good introduction is given in the first recipe of this series, *Calculating various percentages*. Therefore, it is recommended that you read all three recipes in this series in order to get a better picture of the possibilities and specifics of calculating relative percentages, averages, and ranks.

Getting ready

Start SQL Server Management Studio and connect to your SSAS 2016 instance. Click on the **New Query** button and check that the target database is Adventure Works DW 2016.

Here's the query we'll start from:

```
WITH
MEMBER [Measures].[Level] AS
    [Sales Territory].[Sales Territory]
    .CurrentMember.Level.Ordinal
SELECT
    { [Measures].[Level],
        [Measures].[Reseller Sales Amount] } ON 0,
    { [Sales Territory].[Sales Territory].AllMembers } ON 1
FROM
    [Adventure Works]
```

Once executed, the query returns the complete [Sales Territory].[Sales Territory] user hierarchy on rows:

	Level	Reseller Sales Amount
All Sales Territories	0	\$80,450,596.98
Europe	1	\$10,870,534.80
France	2	\$4,607,537.94
Germany	2	\$1,983,988.04
United Kingdom	2	\$4,279,008.83
NA	1	(null)
North America	1	\$67,985,726.81
Canada	2	\$14,377,925.60
United States	2	\$53,607,801.21
Central	3	\$7,906,008.18
Northeast	3	\$6,932,842.01
Northwest	3	\$12,435,076.00
Southeast	3	\$7,867,416.23
Southwest	3	\$18,466,458.79
Pacific	1	\$1,594,335.38
Australia	2	\$1,594,335.38

In columns, we have a little helper, the level ordinal, displayed in the form of a measure. In addition to that, we have the main measure, the Reseller Sales Amount measure. That's the measure we're going to use to calculate the ranks.

This is the same initial query we used in the previous two recipes in this series. Please refer back to the screenshot in the previous two recipes.

We are going to calculate three different ranks: Siblings Rank, Level Rank, and Hierarchy Rank.

How to do it...

Follow these steps to create these three rank calculations:

1. Create the first calculated measure, name it Siblings Rank, and provide the definition for it using the Rank() function and the Siblings function:

```
MEMBER [Measures].[Siblings Rank] AS  
    Rank( [Sales Territory].[Sales Territory].CurrentMember,  
          [Sales Territory].[Sales Territory]  
          .CurrentMember.Siblings,  
          [Measures].[Reseller Sales Amount] )
```

2. Create the second calculated measure, name it Level Rank, and provide the definition for it using the Rank() function and the Level function:

```
MEMBER [Measures].[Level Rank] AS  
    Rank( [Sales Territory].[Sales Territory].CurrentMember,  
          [Sales Territory].[Sales Territory]  
          .CurrentMember.Level.Members,  
          [Measures].[Reseller Sales Amount] )
```

3. Create the third calculated measure, name it Hierarchy Rank, and provide the definition for it using the Rank() function. This time, use a named set for the second argument. Name that set Hierarchy Set:

```
MEMBER [Measures].[Hierarchy Rank] AS  
    Rank( [Sales Territory].[Sales Territory].CurrentMember,  
          [Hierarchy Set],  
          [Measures].[Reseller Sales Amount] )
```

4. Define the set Hierarchy Set as a set of all hierarchy members:

```
SET [Hierarchy Set] AS
    [Sales Territory].[Sales Territory].Members
```

5. Include all three calculated measures on columns and execute the query.

6. Verify that the result matches the following screenshot:

	Level	Reseller Sales Amount	Siblings Rank	Level Rank	Hierarchy Rank
All Sales Territories	0	\$80,450,596.98	1	1	1
Europe	1	\$10,870,534.80	2	2	7
France	2	\$4,607,537.94	1	3	11
Germany	2	\$1,983,988.04	3	5	13
United Kingdom	2	\$4,279,008.83	2	4	12
NA	1	(null)	4	4	16
North America	1	\$67,985,726.81	1	1	2
Canada	2	\$14,377,925.60	2	2	5
United States	2	\$53,607,801.21	1	1	3
Central	3	\$7,906,008.18	3	3	8
Northeast	3	\$6,932,842.01	5	5	10
Northwest	3	\$12,435,076.00	2	2	6
Southeast	3	\$7,867,416.23	4	4	9
Southwest	3	\$18,466,458.79	1	1	4
Pacific	1	\$1,594,335.38	3	3	14
Australia	2	\$1,594,335.38	1	6	14

How it works...

The Rank() function has two variants, one with two arguments, and one with a third:

```
Rank(Member_Expression, Set_Expression)
Rank(Member_Expression, Set_Expression, Numeric Expression)
```

When using the first syntax, where a numeric expression is not specified, the Rank() function simply returns the one-based ordinal position of the first member in the second set argument.

When using the second syntax, where a third numeric expression is specified, the `Rank()` function determines the one-based rank for the specified member in the set according to the results of evaluating the specified numeric expression against the member.

In our example, we have used the second syntax. Let us discuss some specifics of the second syntax and how we used it in our example.

When the third numeric argument is supplied to the `Rank()` function, the `Rank()` function evaluates the numeric expression for the member specified as the first argument and compares it to the members of the set specified as the second argument. The function then determines the 1-based rank of the member in that set according to the results.

All three ranks are for the current member on the rows. Therefore, we have used the same member expression as the first argument to the `Rank()` function:

```
[Sales Territory].[Sales Territory].CurrentMember
```

We have also provided the same numeric expression, `[Measures].[Reseller Sales Amount]`, to the `Rank()` function as the third argument.

The only difference in the three calculations is in the second set expression we provided to the `Rank()` function.

The `Siblings Rank` is calculated against the current member's siblings, or children of the same parent. This is the set expression to get all the current member's siblings:

```
[Sales Territory].[Sales Territory].CurrentMember.Siblings
```

The `Level Rank` is calculated against all members in the same level as the current member's level. This is the set expression to get all members at the current member's level:

```
[Sales Territory].[Sales Territory].CurrentMember.Level.Members
```

Finally, the third rank, the `Hierarchy Rank`, is calculated against all members in that hierarchy. This is the set expression to get all the members in the hierarchy:

```
[Sales Territory].[Sales Territory].Members
```

That is also the only set not dependent on the current context. Notice that we have created a named set, `[Hierarchy Set]`. By creating a named set that is independent of the current context, we have essentially moved it outside the iteration. The query performance has been improved. Notice that we did not do this for the `Siblings Rank` and the `Level Rank` because we couldn't.

The rules are relatively simple. Whenever there's a set that doesn't depend on the current context, it is better to extract it from the calculation and define it as a named set. That way, it will be evaluated only once, after the evaluation of the subselect and slicer, and before the evaluation of axes. During the process of cell evaluation, which is the next phase in the query execution, such a set acts like a constant, which makes the calculations run faster.

On the other hand, when the set's definition references the current context, that is, current members of the hierarchies on columns or rows, we must leave the set inside the calculation, or else our calculation will not be dynamic.

There's more...

In the first variant of the `Rank()` function, where the third numeric expression is not provided, the order of members in the set supplied as the second argument plays a crucial role. The function returns the ordinal position of the first member in the second set.

It is important to remember that, in either variant, the `Rank()` function will not do the sorting for us. If we want the function to return the ranks in a sorted order, then it is up to us to supply a pre-sorted set of members and use it as the second argument.

Tie in ranks

While the three-argument version of the `Rank()` function can produce tied ranks, the two-argument version will never have tied ranks because the two-argument version determines the ordinal order of members in a set and there's never a tie in the ordinal order; all ordinal positions are unique. However, in the three-argument version, the rank position depends on the value of the numeric expression. Occasionally, that value can repeat which is why the ties exist.

For example, the last two rows of the `Hierarchy Rank` column in the previous screenshot both have the value 14 as their rank. Consequently, there's no rank 15 in that column; the sequence continues with 16.

Preserving empty rows

Ranks are never null. They are a dense type of calculation. The consequence is that we need to handle rows where the original measure is empty.

Take a look at the screenshot with the results again and you'll notice that there is a row with the null value for the Reseller Sales Amount, but the ranks themselves are not null. This is something we need to take care of.

First, we can use the `iif()` statement to handle empty rows, just like we did in the previous recipe. Here's an example of how we can correct rank calculations so that they skip rows with empty values:

```
MEMBER [Measures].[Siblings Rank] AS
    iif( IsEmpty( [Measures].[Reseller Sales Amount] ),
        null,
        Rank( [Sales Territory].[Sales Territory]
            .CurrentMember,
            [Sales Territory].[Sales Territory]
            .CurrentMember.Siblings,
            [Measures].[Reseller Sales Amount]
        )
    )
```

This extra layer in our calculation does indeed eliminate the rows where the original measure is empty, making it a good approach. The problem is that the solution is still not a good enough one. Not yet, and we're about to find out why.

The problem lies in the fact that ranks can have holes; they might not be consecutive. A subtle surprise we may not notice at first, but a perfectly understandable behavior once we realize that ranks are actually calculated on a whole set of members, not just the non-empty ones.

While calculating the rank on all members may or may not be what we want, it is more often that we do not want that. In that case, there's still something we can do.

We can make the set in the second argument more compact. We can eliminate all extra members so that our ranks are consecutive and our calculation is faster, because it will operate on a smaller set.

The magic happens in the `NonEmpty()` function. Here's how the modified query could look:

```
WITH
SET [Hierarchy Set] AS
    NonEmpty( [Sales Territory].[Sales Territory].Members,
        { [Measures].[Reseller Sales Amount] } )
MEMBER [Measures].[Level] AS
    iif( IsEmpty( [Measures].[Reseller Sales Amount] ),
        null,
        [Sales Territory].[Sales Territory]
```

```
    .CurrentMember.Level.Ordinal
)
MEMBER [Measures].[Siblings Rank] AS
    iif( IsEmpty( [Measures].[Reseller Sales Amount] ),
        null,
        Rank( [Sales Territory].[Sales Territory]
            .CurrentMember,
            NonEmpty( [Sales Territory].[Sales Territory]
                .CurrentMember.Siblings,
                { [Measures].[Reseller Sales Amount] }
            ),
            [Measures].[Reseller Sales Amount] )
    )
MEMBER [Measures].[Level Rank] AS
    iif( IsEmpty( [Measures].[Reseller Sales Amount] ),
        null,
        Rank( [Sales Territory].[Sales Territory]
            .CurrentMember,
            NonEmpty( [Sales Territory].[Sales Territory]
                .CurrentMember.Level.Members,
                { [Measures].[Reseller Sales Amount] }
            ),
            [Measures].[Reseller Sales Amount] )
    )
MEMBER [Measures].[Hierarchy Rank] AS
    iif( IsEmpty( [Measures].[Reseller Sales Amount] ),
        null,
        Rank( [Sales Territory].[Sales Territory]
            .CurrentMember,
            [Hierarchy Set],
            [Measures].[Reseller Sales Amount] )
    )
)
SELECT
{ [Measures].[Level],
[Measures].[Reseller Sales Amount],
[Measures].[Siblings Rank],
[Measures].[Level Rank],
[Measures].[Hierarchy Rank] } ON 0,
{ [Sales Territory].[Sales Territory].AllMembers } ON 1
FROM
[Adventure Works]
```

From the preceding query, it's evident that we've added the outer `iif()` clause in each calculated member. That's the part that handles the detection of empty rows.

Additionally, we wrapped all sets in a `NonEmpty()` function, specifying that the second argument of that function should be the `Reseller Sales Amount` measure. Notice that we've done it in the named set too, not just for inner sets in `Rank()` functions, but in that case, we applied the `NonEmpty()` function in the set, not inside the `Rank()` function. This is important because, as we said before, the set is invariant to the context and it makes sense to prepare it in full in advance.

Now, the effect of the `NonEmpty()` function may not be visible in three-part variants of the `Rank()` function, especially if there are no negative values, because the negative values come after the zeros and nulls. It is immediately clear when we have discontinuous ranks. Therefore, we're going to make another example, a really simple example using the product colors.

Write the following query:

```
WITH
    SET [Color Set] AS
        [Product].[Color].[Color].Members
    SET [Color Set NonEmpty] AS
        NonEmpty( [Product].[Color].[Color].Members,
            { [Measures].[Internet Sales Amount] } )
MEMBER [Measures].[Level Rank] AS
    iif( IsEmpty( [Measures].[Internet Sales Amount] ),
        null,
        Rank( [Product].[Color].CurrentMember,
            [Color Set] )
    )
MEMBER [Measures].[Level Rank NonEmpty] AS
    iif( IsEmpty( [Measures].[Internet Sales Amount] ),
        null,
        Rank( [Product].[Color].CurrentMember,
            [Color Set NonEmpty] )
    )
SELECT
    { [Measures].[Internet Sales Amount],
        [Measures].[Level Rank],
        [Measures].[Level Rank NonEmpty] } ON 0,
    { [Product].[Color].[Color].Members } ON 1
FROM
    [Adventure Works]
```

This query displays all product colors and their corresponding sales values. The query also contains two named sets, one having all product colors, the other having only the colors with sales. The two calculated measures return ranks, one using the first set and the other using the second named set.

Now execute that query and observe the results:

	Internet Sales Amount	Level Rank	Level Rank NonEmpty
Black	\$8,838,411.96	1	1
Blue	\$2,279,096.28	2	2
Grey	(null)	(null)	(null)
Multi	\$106,470.74	4	3
NA	\$435,116.69	5	4
Red	\$7,724,330.52	6	5
Silver	\$5,113,389.08	7	6
Silver/Black	(null)	(null)	(null)
White	\$5,106.32	9	7
Yellow	\$4,856,755.63	10	8

In the preceding screenshot, the highlighted section shows the adjusted ranks.

The left rank runs from **1** to **10** and occasionally doesn't display the result. The right rank runs from **1** to **8** because the empty rows are excluded in the named set used as its second argument.

Now, imagine we apply the `NON EMPTY` operator to rows. That action would eliminate the grey and silver/black colors. In this situation, only the right rank would return the results as expected in most cases. Now you know how to make the rank work this way, so do it.

One more thing: in the previous query, there was a set of members in rows, including all product colors. Notice that the same set appears in both named sets.

The first named set is defined exactly as the set in rows. The second named set contains non-empty colors only. That definition is actually the equivalent of what we would get in rows if the `NON EMPTY` operator was applied. In short, we can put one of the named sets in rows instead and have a more manageable code.

Ranks in multidimensional sets

The first argument of the `Rank()` function can in fact be a tuple, not just a member, which enables calculation of ranks for multidimensional sets.

What we need to be extra careful about in this case is the dimensionality of the first two arguments. The dimensionality must match. In other words, the order of hierarchies in a tuple must match the order of hierarchies in a set.

Everything that's been said for one-dimensional sets applies here too.

The pluses and minuses of named sets

When named sets are used in calculations, the performance can either benefit from it or suffer because of it. The latter is more often the case. However, this certainly doesn't classify sets in MDX as bad per se, quite the opposite: sets are a very valuable mechanism in MDX, just like the fire in our ordinary life. If you learn to tell the difference between when to use them and when to not, you're safe with named sets and sets in general.

Currently, the SSAS engine is not optimized to run in block computation mode when sets (named sets or set aliases, that is, sets defined in line in MDX expressions) are used as an argument of functions that perform the aggregation of values. Typical examples are the `Sum()` and the `Count()` functions. Those functions are optimized to run in block mode but if you provide a named set or set alias as their argument, you will turn this optimization off and those functions will run in a much slower cell-by-cell mode. This lack of support may change in future releases of SSAS but, for the time being, you should avoid using named sets and set aliases in those functions unless the situation really requires it. This requirement will rarely be mentioned for named sets, but it may be a valid scenario for set aliases if you need to achieve very flexible and dynamic calculations and you're ready to make a compromise in performance as a trade-off.

On the other hand, other functions such as the `Rank()` function can profit from using named sets. This is because a different execution pattern is applied in their case. Let's illustrate this with an example.

Let's suppose that the `Sum()` and `Count()` functions iterate along a vertical line in cell-by-cell mode and compress that line in a dot when operating in the block mode. Naturally, returning a value in a single point is a much faster operation than iterating along the line.

The rank has to be evaluated for each cell; it does not run in block mode. In other words, it has to go along that vertical line anyway. Unfortunately, that's not the entire issue. Along the way, the `Rank()` function has to evaluate the set on which to perform the rank operation, a set which can be visualized as yet another line, this time a horizontal line. The problem is that this new line can change per each dot on the vertical line, which means the engine can anticipate nothing but an irregular surface on which to calculate rank values. This is slow because all of a sudden we have two loops, one for the vertical path and the other for the horizontal. Could this be optimized? Yes, by removing the unnecessary loop again, which, in this case, is the inner loop. Here's how.

When we define a named set and use it inside the `Rank()` function, we're actually telling the SSAS engine that this set is invariant to the current context and as such can be treated as constant; that is, we declare there's a rectangle, not an irregular surface. This way, the engine can traverse the vertical line and not bother with evaluating the horizontal line, which is a kind of block optimization again. In other words, it can perform much better.

Another situation when you might want to use named sets is when you're not aggregating values but instead applying set operations such as the difference or intersection of sets. In that situation, sets also perform well, much better than using the `Filter()` function to do the same thing, for example.

To conclude, named sets are a mixed bag; use them, but with caution. Don't forget you can always test which version of your calculation performs better, the one with named sets or the one without them. The *Capturing MDX queries generated by SSAS frontends* recipe in Chapter 10, *On the Edge* will show you how to test that.

6

MDX for Reporting

In this chapter, we will cover the following recipes:

- Creating a picklist
- Using a date calendar
- Passing parameters to an MDX query
- Getting the summary
- Removing empty rows
- Getting data on the column
- Sorting data by dimensions

Introduction

When reporting with multi-dimensional data using MDX queries, there are usually two approaches. One is to use a parameterized MDX query. Another is to use a concatenated dynamic MDX query. In the parameterized MDX query approach, only the values of parameters are passed from the reporting tool, and the MDX query is in the form of parameterized query. In the concatenated dynamic MDX query approach, the entire query is constructed in the reporting tool with string manipulation.

In the **SQL Reporting Services (SSRS)**, both the parameterization and concatenation dynamic MDX approaches are supported. Most report writers would choose the parameterization approach, just because Reporting Services provide a better user interface for cube browsing, selecting values for parameters, and for testing. But this does not mean that the concatenation dynamic MDX approach is in some way bad. As a matter of fact, the concatenation dynamic MDX approach is often more flexible because report writers can mix the parameters, the reporting tool's scripting language, and MDX expressions together.

In some cases, it's the only choice reporting writers have, for example, when a customized application is built for reporting.

There is another situation that does not fit well into either definition of the previous two approaches. That is when you need to extract multi-dimensional data out from a cube and put them back into relational SQL tables. The data extraction is often done during an automated ETL process. If the front-end tool does not provide user interface for parameterization and MDX queries are constructed with string manipulation, then it can be considered a concatenation dynamic MDX approach.

Although this chapter is not about how to use any of the commercial or customized MDX reporting tools, it is necessary to understand how the reporting tools support these two different approaches. It is also important to know that the problems we are trying to solve in each recipe are relevant to reporting in general, and are applicable to both approaches.

No matter what approach we are taking, turning an ad-hoc report into a dynamic report is a challenging task. There are many special considerations associated with the dynamic nature of reports with dynamic parameters. Through carefully thought-out examples, this chapter introduces new concepts in dynamic reporting, and the challenges and the techniques for efficient report writing.

The purpose of this chapter is to call out issues that are specific to reporting without repeating and overlapping the techniques covered in other chapters. The first four recipes address the specific issues with parameterization. The fifth recipe, *Removing empty rows*, is written with one specific reporting issue in mind, that is, when a calculated measure is added to the column, `NON EMPTY` no longer works. The last two recipes, *Getting data in the column* and *Sorting data by dimensions*, are relevant to both approaches.

In this chapter, we will still use SQL Management Studio (SSMS) for executing MDX queries. Optionally, we will also execute some of the queries in SQL Reporting Services (SSRS), in the Query Editor's design mode. If you have no access to SSRS, you can still go through all the recipes without missing the important points.

Creating a picklist

A **picklist** allows users to select available parameters that can be later passed to the queries for the report. A picklist is commonly used to allow users to select parameters and then pass them to the report's MDX query. The following is an example of a picklist that allows users to pick any resellers:

A picklist serves two purposes: to visually display the captions and to bind each caption to a unique identifier behind the scene. It is this unique identifier that will be passed to the report's MDX query. For the reseller name `A Bike Store`, for example, its unique member name can be either one of the following:

```
[Reseller].[Reseller].&[1]  
[Reseller].[Reseller].[A Bike Store]
```

When users make selections in the picklist, it is not the reseller name that is needed to pass to the MDX query for the report. Instead, it is this fully qualified unique member name for each reseller that is required to pass to the query.

Getting ready

In this recipe for creating a picklist, we are going to create a picklist for all the resellers. When we are writing the MDX query to create the reseller picklist, we want to achieve the following three goals:

- To not show any resellers that never have any sales
- To get each reseller's name, we are going to name this column **ParameterCaption**
- To get each reseller's unique name, we are going to name this column **ParameterValue**

The following are a few examples of the resellers in Adventure Works and the values of **ParameterCaption** and **ParameterValue**:

	ParameterValue	ParameterCaption
A Bike Store	[Reseller].[Reseller].&[1]	A Bike Store
A Great Bicycle Company	[Reseller].[Reseller].&[238]	A Great Bicycle Company
A Typical Bike Shop	[Reseller].[Reseller].&[273]	A Typical Bike Shop

Acceptable Sales & Service	[Reseller].[Reseller].&[370]	Acceptable Sales & Service
Accessories Network	[Reseller].[Reseller].&[553]	Accessories Network
Acclaimed Bicycle Company	[Reseller].[Reseller].&[351]	Acclaimed Bicycle Company

How to do it...

Start SQL Server Management Studio and connect to your SSAS 2016 instance. Click on the **New Query** button and check that the target database is Adventure Works DW 2016.

We will start from this simple MDX query that shows all the resellers and their sales:

```
SELECT  
    [Measures].[Reseller Sales Amount] ON COLUMNS,  
    [Reseller].[Reseller].[Reseller] ON ROWS  
FROM  
    [Adventure Works]
```

This query does not meet any of the previous requirements yet. Let's follow these steps to achieve the three goals:

1. In order to not show any resellers that have no sales, we are going to use the `NONEMPTY()` function with the sales amount as the second parameter. On the `ROWS` axis, we are going to change to the following:

```
NONEMPTY (  
    [Reseller].[Reseller].[Reseller],  
    [Measures].[Reseller Sales Amount]  
) ON ROWS
```

2. To name our two columns as `ParameterCaption` and `ParameterValue`, we will need to use `WITH MEMBER`. Using the `WITH` clause, let's write these two members as the following:

```
WITH  
    MEMBER [Measures].[ParameterValue] AS  
        [Reseller].[Reseller].Currentmember.UniqueName  
    MEMBER [Measures].[ParameterCaption] AS  
        [Reseller].[Reseller].Currentmember.Member_Name
```

3. We no longer need the reseller sales on the COLUMNS axis. We will replace it with ParameterCaption and ParameterValue, as shown in the following code:

```
{ [Measures].[ParameterValue],  
  [Measures].[ParameterCaption] } ON COLUMNS
```

4. This should be your final query:

```
WITH  
  MEMBER [Measures].[ParameterValue] AS  
    [Reseller].[Reseller].Currentmember.UniqueName  
  MEMBER [Measures].[ParameterCaption] AS  
    [Reseller].[Reseller].Currentmember.Member_Name  
  
SELECT  
  { [Measures].[ParameterValue],  
    [Measures].[ParameterCaption] } ON COLUMNS,  
  NONEMPTY (   
    [Reseller].[Reseller].[Reseller],  
    [Measures].[Reseller Sales Amount]  
  ) ON ROWS  
FROM  
  [Adventure Works]
```

When you execute the query in SSMS, you should get the same result as in the following screenshot:

	ParameterValue	ParameterCaption
A Bike Store	[Reseller].[Reseller].&[1]	A Bike Store
A Great Bicycle Company	[Reseller].[Reseller].&[238]	A Great Bicycle Company
A Typical Bike Shop	[Reseller].[Reseller].&[273]	A Typical Bike Shop
Acceptable Sales & Service	[Reseller].[Reseller].&[370]	Acceptable Sales & Service
Accessories Network	[Reseller].[Reseller].&[553]	Accessories Network
Acclaimed Bicycle Company	[Reseller].[Reseller].&[351]	Acclaimed Bicycle Company
Ace Bicycle Supply	[Reseller].[Reseller].&[157]	Ace Bicycle Supply

How it works...

The `WITH` clause is commonly used in MDX query to add more columns to the results. We used `WITH MEMBER` to create two query-scoped calculated members, `ParameterValue` and `ParameterCaption`, and put them on the `COLUMNS` axis, which have become two columns in the results.

We have put these two calculated members in the special dimension `[Measures]`, although that is not the requirement of `WITH MEMBER`. In some front-end reporting tools, such as the SQL Server Reporting Services (SSRS), the special dimension `[Measures]` is the only dimension that is allowed on the `COLUMNS` axis.

Another important function we used in the calculation is the `CurrentMember` function. It is an important function that makes the calculations aware of the context of the query they are being used in. In other words, `CurrentMember` function allows us to write dynamic calculations without hard-coding any member values. In our example, the `CurrentMember` function identifies each reseller on the `ROWS` axis and uses it in the calculation of `ParameterValue` and `ParameterCaption`.

In this recipe, we cannot replace the `NonEmpty()` function with the `NON EMPTY` keyword. The `NON EMPTY` keyword can only remove empty rows when all the values on the `COLUMNS` axis are `NULL`. However, neither `ParameterValue` nor `ParameterCaption` are `NULL`. Please also see the *Removing empty rows* recipe in this chapter for more in depth discussion.

We've also noticed that we did not do any explicit sorting when creating the picklist. This is because the resellers are already sorted in alphabetical order. Please also see the *Sorting data by dimensions* recipe in this chapter for more in-depth discussion about sorting in reports.

There's more...

We've used the `WITH` clause to create two columns: `ParameterValue` and `ParamterCaption`. If we execute the query in SSRS, in the Query Designer's Design Mode, we can now clearly see another column, Reseller, which shows the caption of resellers and is the same as `ParamterCaption`. The Reseller column comes from the Reseller attribute hierarchy on the `ROWS` axis. To reduce the data duplication, we can use the Reseller column and do not need to create the `ParameterCaption` column. However, the advantage of having a fixed column, `ParameterCaption`, against `Reseller` is that a generic picklist widget can be designed for any picklist in the front-end reporting tool. In this recipe, we have also used it for demonstration purposes.

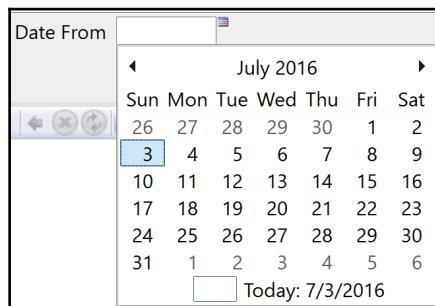

Reseller	ParameterValue	ParameterCaption
A Bike Store	[Reseller].[Reseller].&[1]	A Bike Store
A Great Bicycle Company	[Reseller].[Reseller].&[238]	A Great Bicycle Company
A Typical Bike Shop	[Reseller].[Reseller].&[273]	A Typical Bike Shop
Acceptable Sales & Service	[Reseller].[Reseller].&[370]	Acceptable Sales & Service
Accessories Network	[Reseller].[Reseller].&[553]	Accessories Network
Acclaimed Bicycle Company	[Reseller].[Reseller].&[351]	Acclaimed Bicycle Company
Ace Bicycle Supply	[Reseller].[Reseller].&[157]	Ace Bicycle Supply

- The *Removing empty rows* recipe in this chapter covers how to remove empty rows in reporting in more depth.
- The *Optimizing MDX queries using the NonEmpty() function* recipe is relevant to this recipe. It shows you not only how to use the function, but also the difference between `NonEmpty()` function and `NON EMPTY` keyword.

Using a date calendar

A date calendar is commonly used for users to select a date range. A calendar widget is available in many front-end reporting tools. Many reporting writers prefer to use the calendar widget because it is easy to use in the reporting tool and report users are familiar with it.

Getting ready

Dates that come from the calendar widget are typically in the form of strings, for example, 7/29/2016, which might or might not be a valid date member in the Date dimension.

In this recipe, we will show you how to format the dates from the calendar widget in the reporting tool as a valid date member and then create an MDX query to take the formatted date as a parameter.

In SSMS, if we drag any date from the Date dimension, we will see that a fully qualified key-based date member has the following format:

```
[Date]. [Date].&[20130901]
```

The date representation of 20130901 tells us that any date that is passed into this query needs to be in the yyyyMMdd format.

To format the date string correctly according to the valid format in the Date dimension, in SQL Server Reporting Services (SSRS) you use this code snippet to convert the date into the fully qualified key-based date member:

```
"[Date].[Date].&" + Format(CDate(Parameters!StartDate.Value), "yyyyMMdd")  
+ "]"
```

The CDate() function converts the string that represents a date into a Date type, and the Format() function formats the date as yyyyMMdd. The CDate() function is important, because without it the Format() function would fail.

Our next goal is to create an MDX query to take the formatted date as a parameter.

We will begin with this simple query to show reseller sales for each date:

```
SELECT [Measures].[Reseller Sales Amount] ON COLUMNS,  
      NON EMPTY  
      [Date].[Date].[Date] *  
      [Reseller].[Reseller].[Reseller]  
      ON ROWS  
FROM  
      [Adventure Works]
```

Note that we are using a CROSSJOIN to get the combination of dates and resellers. We are also using the NON EMPTY keyword on the ROWS axis to remove any dates on which no reseller sales exist.

Also note that in Adventure Works DW 2016, the Date dimension is the ordering date. There are also two other dimensions, the Ship Date and the Delivery Date, which are the shipping date and the delivery date, respectively.

How to do it...

Follow these steps to open the Query Editor in SQL Server Management Studio (SSMS):

1. Start SQL Server Management Studio (SSMS) and connect to your SQL Server Analysis Services (SSAS) 2016 instance.
2. Click on the target database Adventure WorksDW 2016 and then right-click on the **New Query** button.
3. In the FROM clause, we are going to replace the cube name [Adventure Works] with a sub-query. In the sub-query, we only need to select a date range in the COLUMNS axis, with a semicolon (;) to separate the start date from the end date. Then, we enclose the sub-query with a pair of parenthesis. For each string of the date member, we will wrap them with the STRTOMEMBER() function with the CONSTRAINED flag.

```
( SELECT
    STRTOMEMBER('[Date].[Date].&[20130901]', CONSTRAINED) :
    STRTOMEMBER('[Date].[Date].&[20131224]', CONSTRAINED) ON COLUMNS
    FROM
    [Adventure Works] )
```

4. Run the final query:

```
SELECT [Measures].[Reseller Sales Amount] ON COLUMNS,
NON EMPTY
    [Date].[Date].[Date] *
    [Reseller].[Reseller].[Reseller]
    ON ROWS
FROM
    (SELECT
        STRTOMEMBER('[Date].[Date].&[20130901]', CONSTRAINED) :
        STRTOMEMBER('[Date].[Date].&[20131224]', CONSTRAINED) ON COLUMNS
        FROM
        [Adventure Works] )
```

5. Here is a screenshot of the query result:

		Reseller Sales Amount
September 29, 2013	Valuable Bike Parts Company	\$29,524.05
September 29, 2013	Vehicle Shop	\$84.50
September 29, 2013	Versatile Sporting Goods Company	\$24.29
September 29, 2013	Vintage Sport Boutique	\$63,235.64
September 29, 2013	Westside Plaza	\$116,153.83
September 29, 2013	Worthwhile Activity Store	\$27,308.22
October 28, 2013	North Bike Company	\$81.56
October 29, 2013	Ace Bicycle Supply	\$923.39
October 29, 2013	Active Transport Inc.	\$72.16
October 29, 2013	Area Sheet Metal Supply	\$21.58
October 29, 2013	Authorized Bike Sales and Rental	\$26,125.85
October 29, 2013	Basic Sports Equipment	\$808.73
October 29, 2013	Bicycle Lines Distributors	\$23,892.77

6. We have hard-coded the date range for testing purposes. Now we need to convert our hard-coded date range into dynamic parameters with @StartDate and @EndDate:

```
SELECT [Measures].[Reseller Sales Amount] ON COLUMNS,
      NON EMPTY
      [Date].[Date].[Date] *
      [Reseller].[Reseller].[Reseller]
      ON ROWS
FROM
  (SELECT
    STRTOMEMBER(@StartDate, CONSTRAINED) : STRTOMEMBER(@EndDate,
CONSTRAINED) ON COLUMNS
  FROM
    [Adventure Works] )
```

How it works...

The important function we used is the STRTOMEMBER() function. Parameters that are passed into an MDX query are either literal strings or numeric values. While the string provided contains a valid MDX member expression, it is not an MDX-qualified member. The purpose of the STRTOMEMBER() function is to resolve the string to an MDX-qualified member, in our case, a Date member

```
STRTOMEMBER('[Date].[Date].&[20130901]', CONSTRAINED)
STRTOMEMBER('[Date].[Date].&[20131224]', CONSTRAINED)
```

The CONSTRAINED flag is an optional flag. When it is used, MDX will return an error message if the string is not built properly and resolved to an invalid member. The CONSTRAINED flag is recommended, because it ensures that the evaluation of the expression is faster and therefore the query performance will be faster as well.

Why did we use the sub-query? What if we just simply add the date range directly in the WHERE clause?

```
SELECT [Measures].[Reseller Sales Amount] ON COLUMNS,
NON EMPTY
    [Date].[Date].[Date] *
    [Reseller].[Reseller].[Reseller]
    ON ROWS
FROM
    [Adventure Works]
WHERE
    STRTOMEMBER('[Date].[Date].&[20130901]', CONSTRAINED) :
    STRTOMEMBER('[Date].[Date].&[20131224]', CONSTRAINED)
```

It will cause this very common error in MDX:

The Date hierarchy already appears in the Axis1 axis.

To avoid this error, we could have replaced the Date attribute hierarchy in the ROWS axis with the Calendar Date hierarchy. So, this query is also valid:

```
SELECT [Measures].[Reseller Sales Amount] ON COLUMNS,
NON EMPTY
[Date].[Calendar Date].[Date] *
[Reseller].[Reseller].[Reseller]
ON ROWS
FROM
[Adventure Works]
WHERE
STRTOMEMBER('[Date].[Date].&[20130901]', CONSTRAINED) :
STRTOMEMBER('[Date].[Date].&[20131224]', CONSTRAINED)
```

What about the @ sign in the parameter name @StartDate and @EndDate? In query languages such as SQL, the @ sign is reserved for parameters. This tradition is also used in many reporting tools. If you are using a customized front-end reporting tool, a parameter name does not need to follow this tradition, for example, you can use [<StartDate>], which will be replaced by the actual value of the start date during the query execution. The point is that the dynamic parameters' names need to follow the rules and traditions of the reporting tool, and not the rules of MDX queries.

There's more...

Because both SSRS and MDX use VBA functions for string manipulation, we might be tempted to use the same code snippet directly in MDX to format the date. However, this will not work because CDATE() is not supported in MDX.

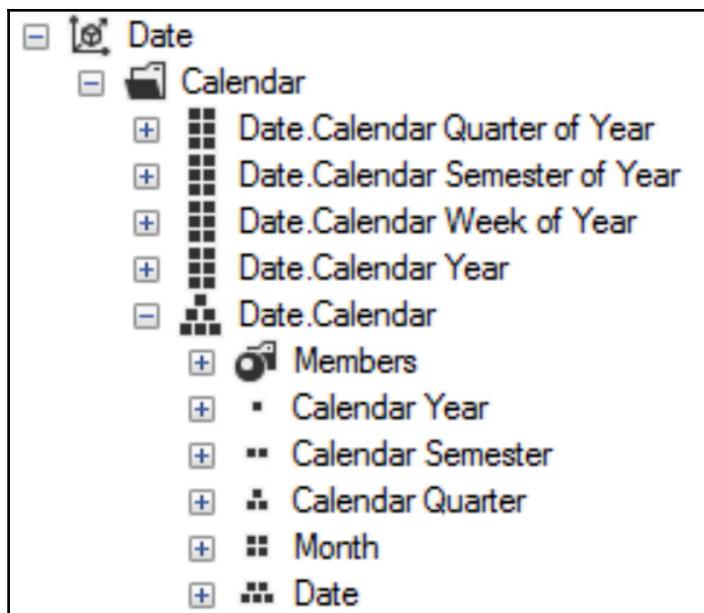

When the CONSTRAINED flag is used in the STRTOMEMBER() function, MDX will return an error message similar to the following message if the string is not built properly and resolved to an invalid member. This also happened when a date that is not in the Date dimension is passed as a parameter. When a calendar widget is used, users could have picked a future date, which will cause MDX to return an error message similar to the following. To avoid this situation, an alternative in the next section can be considered. Because all dates for users to pick are valid members on the Date dimension, we avoid showing dates in the future.

The restrictions imposed by the CONSTRAINED flag in the STRTOMEMBER function were violated

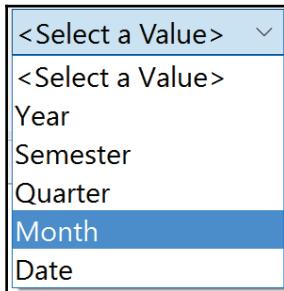

Alternative – allowing users to select by Date hierarchies

The previous recipe has shown how to use the calendar widget in the reporting tool in order to allow users to pick a date range and pass them as date parameters to an MDX query. This is only one approach for doing so, though.

Another way is to make use of the user hierarchies in the `Date` dimension. Almost every cube has a `Date` dimension, and every `Date` dimension has some user hierarchies. The hierarchies, such as the `Calendar` hierarchy as shown in the following screenshot, in the **Adventure Works DW 2016 Multidimensional-EE** allow users to browse the cube with the natural roll-up relationship among `Date`, `Month`, `Calendar Quarter`, `Calendar Semester`, and `Calendar Year`.

Cube users are familiar with this type of relationship and sometimes prefer to pick dates by the different levels in the hierarchy. For example, **Month** is one of the levels in the **Calendar** hierarchy. They might want to be able to pick from the available months in the Date dimension.

The picklist for months can be constructed as shown in the following screenshot:

In order to pass the months as valid date parameters to an MDX query, we would also need to have the fully qualified month value. For example, for the month of September 2014, the fully qualified date member is:

[Date].[Calendar].[Month].&[2014]&[9]

Although it is not difficult to use MDX queries to get all the months in the Date dimension, using one single MDX query to handle all the possible levels in the hierarchy can be challenging.

Using an SQL query or stored procedure in this case is more productive. A snippet of the SQL code is as follows:

```
IF @Reporting_Level = 'Month'
SELECT
    DISTINCT '[Date].[Calendar].[Month].&['
        + CAST([CalendarYear] AS CHAR(4)) + ']' & [
        + CAST([MonthNumberOfYear] AS VARCHAR(2)) + ']' AS ParameterValue
    , [EnglishMonthName] + Space(1) + CAST([CalendarYear] AS CHAR(4)) AS
ParameterCaption
FROM
    [dbo].[DimDate]
WHERE
    [FullDateAlternateKey] <= GetDate()
ORDER BY 1 DESC
```

The result of the SQL query is shown in the following screenshot:

	ParameterValue	ParameterCaption
1	[Date].[Calendar].[Month].&[2014]&[9]	September 2014
2	[Date].[Calendar].[Month].&[2014]&[8]	August 2014
3	[Date].[Calendar].[Month].&[2014]&[7]	July 2014
4	[Date].[Calendar].[Month].&[2014]&[6]	June 2014
5	[Date].[Calendar].[Month].&[2014]&[5]	May 2014
6	[Date].[Calendar].[Month].&[2014]&[4]	April 2014
7	[Date].[Calendar].[Month].&[2014]&[3]	March 2014

It's this **ParameterValue** field that will be used to pass to an MDX query. The **ParameterCaption** is used to display in the picklist.

See also

- The previous recipe, *Creating a picklist*, is relevant to this recipe. It shows how to create a picklist that has both **ParameterValue**, which is passed as a parameter to an MDX query, and **ParameterCaption**, which is displayed in the picklist.
- The next recipe, *Passing parameters to an MDX Query*, is also relevant to this recipe. It shows how to use **STRTOSET()** function to pass a list as parameters to an MDX query.

Passing parameters to an MDX query

In this recipe, we will consider two questions when passing parameters to an MDX query. One is the location of the parameters in the query, and the other is when to use STRTOMEMBER() function and when to use STRTOSET() function.

Where should we put the parameter(s) in the MDX query? We actually have the freedom to put them anywhere - in the WITH clause, on the COLUMNS and ROWS axes, in the WHERE clause, and in the subquery. In the previous recipe, *Using a date calendar*, we decided to put the parameters in the sub-query. In this recipe, we are going to expand that MDX query and add one more parameter on the ROWS axis. We will also move the date member parameter from the subquery to the WHERE clause.

The STRTOSET() function works in the same way as the STRTOMEMBER() function. The only difference is that the STRTOSET() function resolves the string into a set, while the STRTOMEMBER() function resolves the string into a member. In this recipe, we will use both of these functions.

Getting ready

We will make an assumption that you have built two picklists in the reporting tool. One is for the Date dimension and another one is for the Reseller dimension.

We are going to name the date parameter @Month and the reseller parameter @Reseller. We are only going to allow one month to be selected at a time, but we will allow multiple resellers to be selected. As the result of our assumption, the @Month parameter will be a string that contains a month member and the @Reseller parameter will be a string that contains a set of reseller members. The following are the examples:

```
'[Date].[Calendar].[Month].&[2013]&[7]'  
'{[Reseller].[Reseller].&[157], [Reseller].[Reseller].&[199]}'
```

In this recipe, we are going to use the preceding two parameters, @Month and @Reseller, in an MDX query to generate a report, as shown in the following screenshot.

	Reseller Sales Amount
Cycling Goods	\$11,546.63
Distance Bikes	\$323.99
Efficient Cycling	\$1,337.60
Eighth Bike Store	\$25,411.36
Endurance Bikes	\$356.90
Every Bike Shop	\$10,771.54
Excellent Bikes	\$28,644.32

To construct the MDX query, we are going to use the previous examples of the two parameters for testing purposes.

How to do it...

Start SQL Server Management Studio and connect to your SSAS 2016 instance. Click on the **New Query** button and check that the target database is Adventure Works DW 2016.

Copy the previous example of the month parameter and wrap the STRTOMEMBER() function around it with the CONSTRAINED flag. Then, put the code in the WHERE clause.

```
WHERE  
STRTOMEMBER(' [Date].[Calendar].[Month].&[2013]&[7]', CONSTRAINED)
```

1. Copy the previous example of the reseller set parameter and wrap the STRTOSET() function around it with the CONSTRAINED flag. Then put the code in the ROWS axis and add the NON EMPTY keyword.

```
NON EMPTY  
STRTOSSET(' {[Reseller].[Reseller].&[157], [Reseller].[Reseller].&  
[199]}', CONSTRAINED)  
ON ROWS
```

2. Copy the previous example of the month parameter and wrap the STRTOMEMBER() function around it with the CONSTRAINED flag. Then, put the code in the WHERE clause.

WHERE

```
STRTOMEMBER('[Date].[Calendar].[Month].&[2013]&[7]', CONSTRAINED)
```

3. Copy the previous example of the reseller set parameter and wrap the STRTOSET() function around it with the CONSTRAINED flag. Then, put the code in the ROWS axis and add the NON EMPTY keyword.

```
NON EMPTY  
STRTOSSET('{[Reseller].[Reseller].&[157],  
[Reseller].[Reseller].&[199]}', CONSTRAINED)  
ON ROWS
```

4. Add the [Reseller Sales Amount] measure on the COLUMNS axis. Here is the final query:

```
SELECT [Measures].[Reseller Sales Amount] ON COLUMNS,  
NON EMPTY  
STRTOSSET('{[Reseller].[Reseller].&[157],  
[Reseller].[Reseller].&[199]}', CONSTRAINED)  
ON ROWS  
FROM  
[Adventure Works]  
WHERE  
STRTOMEMBER('[Date].[Calendar].[Month].&[2013]&[7]', CONSTRAINED)
```

5. The result should be as shown in the following screenshot:

	Reseller Sales Amount
Ace Bicycle Supply	\$1,391.99
Authorized Bike Sales and Rental	\$24,025.39

6. We have hard-coded the parameters for testing purposes. Now we need to replace them with @Month and @Reseller:

```
SELECT [Measures].[Reseller Sales Amount] ON COLUMNS,  
NON EMPTY  
STRTOSET(@Reseller, CONSTRAINED)  
ON ROWS  
FROM  
[Adventure Works]  
WHERE  
STRTOMEMBER(@Month, CONSTRAINED)
```

How it works...

Query parameters are report filters. Just as filters can be put anywhere in an MDX query, we can put query parameters anywhere in an MDX query too. We have chosen to put the @Reseller parameter right on the ROWS axis, because reseller is a data point that we need to show in the report. There is no need to hide it in the slicer or in the sub-query.

On the other hand, the @Month parameter is purely a filter and not a data point in the report. We can hide it either in the slicer or in the sub-query, or include it in both places. We have chosen to put it in the slicer for two purposes. One is to just demonstrate that parameters can be in any place in an MDX query. The second is because the slicer provides query context.

The STRTOMEMBER() and STRTOSET() functions are typically used when an MDX query is parameterized. Both work the same way and both take an optional CONSTRAINED flag. The only difference is that the STRTOSET() function resolves the string into a set, while the STRTOMEMBER() function resolves the string into a member.

Another way to easily remember when to use which function is to remember that the STRTOMEMBER() function should be used when the picklist allows only one choice at a time, and the STRTOSET() function should be used when the picklist allows multi-selections.

There's more...

When we write parameterized MDX queries, constructing and testing the MDX queries should really be in the same step.

To construct parameterized MDX queries, it is always easier to use the Query Editor in SSMS and hard-code the parameters with some examples first. Then, you can replace the hard-coded values with @ParameterName. However, this requires you to find good parameters values for testing.

Sometimes, in order to save time on finding specific test values, we can directly use a member or a set for testing. For example, the following RESELLER set:

```
[Reseller].[Reseller].[Reseller]
```

This can be used directly in the MDX for testing purposes, rather than using:

```
STRTOSET('{[Reseller].[Reseller].&[157], [Reseller].[Reseller].&[199]}',  
CONstrained)
```

But at the end, we still need to replace it with the STRTOSET() or STRTOMEMBER() function in the final parameterized query.

```
STRTOSET(@ParameterName, CONSTRAINED)
```

When we choose to use a sample set for testing, we must not forget that the set string must be a valid MDX-formatted string. For a set, that means we must use {} to wrap around the expression.

The following code will work as expected:

```
STRTOSET('{[Reseller].[Reseller].&[157], [Reseller].[Reseller].&[199]}',  
CONstrained)
```

The following code will not work without the {} around the two reseller members:

```
STRTOSET('[Reseller].[Reseller].&[157], [Reseller].[Reseller].&[199]',  
Constrained)
```

We have stated that the reporting tools will pass a multi-selection parameter, such as the reseller, with {} around the list of resellers:

```
'{[Reseller].[Reseller].&[157], [Reseller].[Reseller].&[199]}'
```

Reporting tools such as SSRS will automatically wrap the {} around a multi-selection parameter if the data source is an Analysis Services database. So in your MDX query, you can safely assume that they contain valid set expressions. If you are putting strings together in a customized reporting tool, you have to make sure that {} is not missing.

Getting the summary

The advantages of a multi-dimensional cube are that the data is pre-aggregated and that there is a lot of metadata that we can use for calculations. There is no need to re-aggregate data at the query time, and we have pre-defined calculation formulas in the cube. Not to mention that all metrics are formatted in the cube. Reporting tools should take advantage of this instead of reinventing the wheel.

It is always a good idea to rely on MDX queries to get the correct aggregation no matter what tool you use, so that the need to aggregate in the reporting tool is eliminated.

Visual totals are totals at the end of a column or row that add up all of the items visible in the column or row. By default, when placing the `All` member in the query, totals including both visual and non-visual items will be displayed for most pivot tables. For MDX queries that do not show all the items, this default behavior is misleading because we only want the totals to include the visual items.

Getting ready

Let's examine this simple query to see the default behavior. Suppose we have two parameters, `@Month` and `@Product`, and they have values as follows:

```
'[Date].[Calendar].[Month]&[2013]&[7]'
```

```
'{ [Product].[Product Categories].[Accessories], [Product].[Product Categories].[Clothing] }'
```

Let's wrap the `STRTOMEMBER()` and `STRTOSET()` functions around the parameters with the `CONSTRAINED` flag. For the `@Month` parameter, let's put it in the `WHERE` clause. For the `@Product` parameter, let's add `[All Products]` to the set and create a named set, `[Visual Total]`:

Now, let's put these three measures on the COLUMNS. The amount is a fully additive measure, and the two ratios are semi-additive calculated measures.

```
[Measures].[Internet Sales Amount]  
[Measures].[Internet Ratio to All Products]  
[Measures].[Internet Ratio to Parent Product]
```

Here is the final MDX query we put together:

```
WITH SET [Visual Total] AS  
{ [Product].[Product Categories].[All Products],  
  STRTOSET('{' + [Product].[Product  
Categories].[Accessories] + ',' + [Product].[Product Categories].[Clothing]}',  
CONSTRINED)  
}  
  
SELECT  
{ [Measures].[Internet Sales Amount],  
  [Measures].[Internet Ratio to All Products],  
  [Measures].[Internet Ratio to Parent Product] } ON COLUMNS,  
NON EMPTY [Visual Total] ON ROWS  
FROM  
  [Adventure Works]  
WHERE  
  STRTOMEMBER(' [Date].[Calendar].[Month].&[2013]&[7] ', CONSTRINED)
```

When executed in SSMS, this query produces the following result:

	Internet Sales Amount	Internet Ratio to All Products	Internet Ratio to Parent Product
All Products	\$1,371,675.81	100.00%	100.00%
Accessories	\$58,001.76	4.23%	4.23%
Clothing	\$29,486.64	2.15%	2.15%

It's obvious that this [All Products] member we added to the set gave us misleading totals that include both the visible Accessories and Clothing, and also other invisible product categories.

In this recipe, we are going to explore the `VisualTotals()` function to see how it can aggregate totals that only include the visible items. The word *visual* here implies that the aggregation will include only the visible items.

How to do it...

Start SQL Server Management Studio and connect to your SSAS 2016 instance. Click on the **New Query** button and check that the target database is Adventure Works DW 2016.

Copy the MDX query from the Getting ready section and paste into the query window.

1. Let's wrap `VisualTotals()` around the named set `[Visual Total]` and add a naming pattern '`Total - *`' for the visual totals:

```
WITH SET [Visual Total] AS
VisualTotals(
    { [Product].[Product Categories].[All Products],
      STRTOSET(' {[Product].[Product Categories].[Accessories],
[Product].[Product Categories].[Clothing]}', CONSTRAINED)
    },
    'Total - *'
)
This is the final query:

WITH SET [Visual Total] AS
VisualTotals(
    { [Product].[Product Categories].[All Products],
      STRTOSET(' {[Product].[Product Categories].[Accessories],
[Product].[Product Categories].[Clothing]}', CONSTRAINED)
    },
    'Total - *'
)

SELECT
    { [Measures].[Internet Sales Amount],
      [Measures].[Internet Ratio to All Products],
      [Measures].[Internet Ratio to Parent Product] } ON COLUMNS,
    NON EMPTY [Visual Total] ON ROWS
FROM
    [Adventure Works]
WHERE
    STRTOMEMBER(' [Date].[Calendar].[Month].&[2013]&[7]', CONSTRAINED)
```

2. When executed in SSMS, the query produces the same result as in the following screenshot:

	Internet Sales Amount	Internet Ratio to All Products	Internet Ratio to Parent Product
Total - All Products	\$87,488.40	100.00%	100.00%
Accessories	\$58,001.76	66.30%	66.30%
Clothing	\$29,486.64	33.70%	33.70%

This same [All Products] member now gives us totals that include only the visible **Accessories** and **Clothing**. This is true for both the fully-additive and semi-additive calculated measures. Notice that the ratios for **Accessories** and **Clothing** are also correctly calculated against the **All**, that is, the parent product.

How it works...

By dynamically totaling child members in a specified set, the `VisualTotals()` function returns a set with dynamic totals. Here is its syntax:

```
VisualTotals(Set_Expression, Pattern)
```

The `Pattern` is an optional parameter used to name the parent member in the result set. In our query, we used '`Total - *`'. Replacing the `*` by the `All` member name `All Products`, our total row has become `Total - All Products`.

We used a set expression that contains members at the `Category` level within a single `Product` dimension. But we don't need to limit the members in one level. As shown in the *Getting visual totals at multiple levels* section, the `VisualTotals()` function works well as long as we use one single dimension and members have an ancestor-descendant relationship.

The `VisualTotals()` function totals the values of child members in the specified set and ignores child members that are not in the set when calculating the totals. Totals are visually totaled for the sets ordered in hierarchy order.

There's more...

This recipe has demonstrated how to use the `VisualTotals()` function to aggregate metrics that are either fully-additive or semi-additive to include only the visible items in the report. This doesn't mean that there will never be cases when aggregations should also include non-visual items. When we do need to show non-visual totals, we can use the `NON VISUAL` keyword. The `NON VISUAL` keyword can be used to produce non-visual totals on rows or columns, or both. An MSDN article on *Visual Totals and Non Visual Totals* can be viewed at <http://tinyurl.com/zb2ojds>.

Getting visual totals at multiple levels

We have kept the query simple by showing only one level of totals. In the real world, we often have to group and aggregate our data at multiple levels. To make our reports more visually appealing and easy to read, we also need to visually differentiate data at different levels.

In Adventure Works DW 2016 SSAS, the Product dimension has a `Product Categories` hierarchy with three levels: `Category`, `Subcategory`, and `Product`. In order to produce a report, such as the following, where `Total - All Products`, `Category`, and `Subcategory` are highlighted using different hues of color grey and each level is indented according to its level, we will need to accomplish two more tasks:

1. From `Category`, we need to get all the subcategories and all the products.

2. We need to add a column, **Level**, to the report.

	Internet Sales Amount	Internet Ratio to All Products	Internet Ratio to Parent Product	Level
Total - All Products	\$87,488.40	100.00%	100.00%	0
Accessories	\$58,001.76	66.30%	66.30%	1
Bike Racks	\$2,400.00	2.74%	4.14%	2
Hitch Rack - 4-Bike	\$2,400.00	2.74%	100.00%	3
Bike Stands	\$2,703.00	3.09%	4.66%	2
All-Purpose Bike Stand	\$2,703.00	3.09%	100.00%	3
Bottles and Cages	\$4,798.28	5.48%	8.27%	2
Mountain Bottle Cage	\$1,768.23	2.02%	36.85%	3
Road Bottle Cage	\$1,258.60	1.44%	26.23%	3
Water Bottle - 30 oz.	\$1,771.45	2.02%	36.92%	3
Cleaners	\$747.30	0.85%	1.29%	2
Bike Wash - Dissolver	\$747.30	0.85%	100.00%	3
Fenders	\$4,417.98	5.05%	7.62%	2
Fender Set - Mountain	\$4,417.98	5.05%	100.00%	3
Helmets	\$17,984.86	20.56%	31.01%	2
Sport-100 Helmet, Black	\$5,388.46	6.16%	29.96%	3
Sport-100 Helmet, Blue	\$5,668.38	6.48%	31.52%	3
Sport-100 Helmet, Red	\$6,928.02	7.92%	38.52%	3
Hydration Packs	\$3,519.36	4.02%	6.07%	2
Hydration Pack - 70 oz.	\$3,519.36	4.02%	100.00%	3
Tires and Tubes	\$21,430.98	24.50%	36.95%	2
HL Mountain Tire	\$4,410.00	5.04%	20.58%	3
HL Road Tire	\$2,477.60	2.83%	11.56%	3
LL Mountain Tire	\$1,799.28	2.06%	8.40%	3
LL Road Tire	\$1,805.16	2.06%	8.42%	3
MI Mountain Tire	\$3,178.94	3.63%	14.83%	3

To accomplish the first task, all we need to do is wrap the DESCENDANTS() function around the parameter:

```
DESCENDANTS (STRTOSET (@Parametername))
```

To accomplish the second task, we can use the `Ordinal` function on each member of the hierarchy.

```
MEMBER [Measures].[Level] AS
    IIF(
        [Measures].[Internet Sales Amount] = 0,
        NULL,
        [Product].[Product Categories].CurrentMember.Level.Ordinal
    )
```

We will also wrap it around an `IIF` statement to force it to `NULL` when the sales amount is null. This will allow us to continue to use the `NON EMPTY` keyword on the `ROWS` to remove empty rows.

Here is the query that we put together to accomplish the two tasks:

```
WITH
SET [Visual Total] AS
    VisualTotals(
        { [Product].[Product Categories].[All Products],
            DESCENDANTS(STRTOSET(' {[Product].[Product
Categories].[Accessories], [Product].[Product Categories].[Clothing]}')) }
        ,
        'Total - *'
    )
MEMBER [Measures].[Level] AS
    IIF([Measures].[Internet Sales Amount] = 0, NULL, [Product].[Product
Categories].CurrentMember.Level.Ordinal)
SELECT
    { [Measures].[Internet Sales Amount],
        [Measures].[Internet Ratio to All Products],
        [Measures].[Internet Ratio to Parent Product],
        [Measures].[Level] } ON COLUMNS,
    NON EMPTY [Visual Total] ON ROWS
FROM
    [Adventure Works]
WHERE
    STRTOMEMBER(' [Date].[Calendar].[Month].&[2013]&[7] ', CONSTRAINED)
```

How the report is created with visual effect is totally up to the front-end reporting tool. At the minimum, the MDX query provided enough information to the frontend tool.

Removing empty rows

We have addressed some specific issues with parameterized MDX queries in the first four recipes. This recipe is written with one specific reporting issue in mind, that is, when a calculated measure is added to the column, NON EMPTY no longer works.

Adding query-scoped calculated measures to the COLUMN axis is one way to place more data points and more headers on the report. However, report writers often find that empty rows start to pop out in the report as soon as the calculated measure is placed on the COLUMN axis.

Let's start with a query to see the problem first.

Getting ready

Let's start from this query with these two filters: the subcategory socks and a date range:

```
[Product].[Product Categories].[Subcategory].[Socks]  
[Date].[Calendar].[Date].&[20130723]:[Date].[Calendar].[Date].&[20130731]
```

The following query is displaying three profits on the columns, as well as the subcategory and the date on the rows.

```
WITH SET [Profit] AS{ [Measures].[Internet Gross Profit],  
                      [Measures].[Reseller Gross Profit],  
                      [Measures].[Gross Profit]  
                    }  
  
SELECT  
    [Profit] ON 0,  
    NON EMPTY  
    [Product].[Product Categories].[Subcategory].[Socks] *  
    [Date].[Calendar].[Date] ON 1  
FROM  
  ( SELECT  
    [Date].[Calendar].[Date].&[20130723]:[Date].[Calendar].[Date].&[20130731]  
  ON 0  
  FROM  
    [Adventure Works]  
 )
```

Note that we are not wrapping the filters in STRTOMEMBER() or STRTOSET() functions. This is for two reasons. The first is that we do not want to repeat what has already been covered in previous recipes, and the second is that the issue in this recipe is common in both parameterized and concatenated dynamic MDX queries.

Another thing worth noticing is that we used a named set [Profit], which is created with reuse in mind. For reuse purposes, named sets are commonly created either in the cube's MDX script or in MDX queries. In this recipe, we will see how the named set [Profit] is reused.

When executed, the result is as follows. Notice that July 25, 2013 is not in the result set. This is because July 25, 2013 has no profit at all; the NON EMPTY keyword has removed it.

		Internet Gross Profit	Reseller Gross Profit	Gross Profit
Socks	July 23, 2013	\$11.26	(null)	\$11.26
Socks	July 24, 2013	\$28.14	(null)	\$28.14
Socks	July 26, 2013	\$11.26	(null)	\$11.26
Socks	July 27, 2013	\$28.14	(null)	\$28.14
Socks	July 28, 2013	\$11.26	(null)	\$11.26
Socks	July 29, 2013	\$5.63	(null)	\$5.63
Socks	July 30, 2013	\$16.88	(null)	\$16.88
Socks	July 31, 2013	\$5.63	\$462.13	\$467.76

Many reports have a drill-through feature that allows users to click on a hyperlink to go to another report linked by a key value. In this recipe, we are going to assume that a key value for the date is needed for the report so that users can go to another report that is linked by the date. For example, for the date July 23, 2013, a key value of 20130723 is needed.

The common way to do this is to create the date key value as a calculated measure using the WITH clause, as shown in the following code, and then add it to COLUMNS.

```
MEMBER [Measures].[Date Key] AS  
[Date].[Calendar].CurrentMember.Member_Key
```

Here is the query required to add a calculated [Measures].[Date Key] to COLUMNS:

```

WITH
SET [Profit] AS
{ [Measures].[Internet Gross Profit],
[Measures].[Reseller Gross Profit],
[Measures].[Gross Profit]
}
MEMBER [Measures].[Date Key] AS
[Date].[Calendar].CurrentMember.Member_Key

SELECT {
[Measures].[Date Key],
[Profit] } ON 0,
NON EMPTY
[Product].[Product Categories].[Subcategory].[Socks] *
[Date].[Calendar].[Date] ON 1
FROM
( SELECT
[Date].[Calendar].[Date].&[20130723]:[Date].[Calendar].[Date].&[20130731]
ON 0
FROM
[Adventure Works]
)

```

		Date Key	Internet Gross Profit	Reseller Gross Profit	Gross Profit
Socks	July 23, 2013	20130723	\$11.26	(null)	\$11.26
Socks	July 24, 2013	20130724	\$28.14	(null)	\$28.14
Socks	July 25, 2013	20130725	(null)	(null)	(null)
Socks	July 26, 2013	20130726	\$11.26	(null)	\$11.26
Socks	July 27, 2013	20130727	\$28.14	(null)	\$28.14
Socks	July 28, 2013	20130728	\$11.26	(null)	\$11.26
Socks	July 29, 2013	20130729	\$5.63	(null)	\$5.63
Socks	July 30, 2013	20130730	\$16.88	(null)	\$16.88
Socks	July 31, 2013	20130731	\$5.63	\$462.13	\$467.76

We notice that as soon as we add the date key, the empty row July 25, 2013 showed up in the report. NON EMPTY no longer works because the calculated date key is not NULL for July 25, 2013. The calculated date key has a value for every date regardless if the date has profit or not.

Next, we are going to modify how [Measures].[Date Key] is calculated in order to continue to use NON EMPTY to remove empty rows. Remember that we will also see how the named set [Profit] is reused.

How to do it...

Start SQL Server Management Studio and connect to your SSAS 2016 instance. Click on the **New Query** button and check that the target database is Adventure Works DW 2016.

In the calculation of [Measures].[Date Key], we are going to add an IIF condition: COUNT([Profit], EXCLUDEEMPTY). If this condition is zero, the calculation will be NULL; otherwise, use the original formula.

```
MEMBER [Measures].[Date Key] AS  
    IIF( COUNT( [Profit], EXCLUDEEMPTY ) = 0, NULL,  
        [Date].[Calendar].CurrentMember.Member_Key  
    )
```

1. All other parts of the query will remain the same, including the NON EMPTY keyword. Here is the final query:

```
WITH  
SET [Profit] AS  
{ [Measures].[Internet Gross Profit],  
[Measures].[Reseller Gross Profit],  
[Measures].[Gross Profit]  
}  
MEMBER [Measures].[Date Key] AS  
    IIF( COUNT( [Profit], EXCLUDEEMPTY ) = 0, NULL,  
        [Date].[Calendar].CurrentMember.Member_Key  
    )  
  
SELECT {  
    [Measures].[Date Key],  
    [Profit] } ON 0,  
NON EMPTY  
    [Product].[Product Categories].[Subcategory].[Socks] *  
    [Date].[Calendar].[Date]  
ON 1
```

```
FROM
  ( SELECT
    [Date]. [Calendar]. [Date] .& [20130723] : [Date]. [Calendar]. [Date] .& [20130731]
  ON 0
    FROM
      [Adventure Works]
  )
```

2. When executed, the previous query should remove the empty row July 25, 2013. You should get the same result as in the screenshot from the *Getting ready* section.

How it works...

The `IIF` condition creates two branches depending on the condition. We used it to set one branch of the `[Date Key]` to `NULL` when the count of the named set `[Profit]` is zero. In this book, we have discussed in several places the importance of keeping the cube space sparse. This allows the empty rows to be removed by either the `NON EMPTY` keyword or the `NONEMPTY()` function. When adding a key value to the column of a report for linking to a sub-report, using the `IIF` condition to set one branch of the value to `NULL` is a good way to keep the key value sparse too.

Another unique issue in many MDX reports is that business usually groups certain measures, either calculated or regular, into related categories. In this recipe, we group two profit measures and one calculated profit into a named set: `[Profit]`. As a matter of fact, the named set should be defined in MDX script in the cube. This is not only for convenience, but also for consistency across different reporting tools and different reports.

There is another advantage of defining these three profit measures as a named set - we no longer need to hard code the name of each measure. This also gives us an easy way to check if all the profits are null by using the `COUNT()` function.

Checking empty sets

Essentially, we have turned the issue of removing empty rows into checking and removing sets. In this recipe, we have used the `COUNT()` function to check empty sets. It returned zero when the set (all three profits) is empty, otherwise it will return 1, 2, or 3, depending on how many profit measures are not empty.

The Count () function returns the number of cells in a set. It has a standard syntax as follows. The EXCLUDEEMPTY or INCLUDEEMPTY flag in the standard syntax is optional.

```
Count (Set_Expression, EXCLUDEEMPTY | INCLUDEEMPTY)
```

It also has an alternate syntax:

```
Set_Expression.Count
```

The important thing to remember about the Count () function is that we must use the standard syntax with the EXCLUDEEMPTY flag in order to exclude empty cells.

There's more...

Checking an empty set is not the only way to remove empty rows for reports. Another way is to replace the NON EMPTY keyword with the NONEMPTY () function, as shown in the following MDX code:

```
NONEMPTY (
    [Product].[Product Categories].[Subcategory].[Socks] *
    [Date].[Calendar].[Date],
    [Profit]
)
```

We will keep the date key calculation without using the IIF condition. Here is the final query:

```
WITH
SET [Profit] AS
{
    [Measures].[Internet Gross Profit],
    [Measures].[Reseller Gross Profit],
    [Measures].[Gross Profit]
}
MEMBER [Measures].[Date Key] AS
    [Date].[Calendar].CurrentMember.Member_Key

SELECT {
    [Measures].[Date Key],
    [Profit] } ON 0,
NONEMPTY (
    [Product].[Product Categories].[Subcategory].[Socks] *
    [Date].[Calendar].[Date],
    [Profit]
) ON 1
FROM
(
    SELECT
```

```
[Date].[Calendar].[Date].&[20130723]:[Date].[Calendar].[Date].&[20130731]
ON 0
FROM
    [Adventure Works]
)
```

The query should also remove the empty row July 25, 2013 from the report.

Trouble with zeros

If any of the three profit measures has a value of zero instead of NULL, neither of the preceding two approaches would be able to remove it. This is because zero is not considered empty by the COUNT() function, nor by the NONEMPTY() function.

We can add an IIF condition for each measure in the set to turn zero into a NULL value:

```
SET [Profit] AS
    { IIF([Measures].[Internet Gross Profit] = 0, NULL, [Measures].[Internet
    Gross Profit]),
        IIF([Measures].[Reseller Gross Profit] = 0, NULL, [Measures].[Reseller
    Gross Profit]),
        IIF([Measures].[Gross Profit] = 0, NULL, [Measures].[Gross Profit])
    }
```

If we define this set in the MDX script in the cube, no changes are needed in the reporting writing, and either the COUNT() function or the NONEMPTY() function will be able to remove empty rows. Again, we have avoided hard-coding any of the individual measures.

See also

- The recipe *Optimizing MDX queries using the NonEmpty() function* is relevant to this recipe. It shows not only how to use the function, but also the difference between the NonEmpty() function and the NON EMPTY keyword.

Getting data on the column

This chapter will discuss two issues about getting data on the column. By this, we mean controlling the data shape in the results. One issue is about controlling the report headers in the results, and another issue is with how to physically put data on the column.

Reports are essentially one dimensional in the sense that both **COLUMNS** and **ROWS** axes from an MDX query will become columns or headers (columns and headers are used interchangeably in this chapter) in the report. Most of the reporting tools require the report shape to be pre-defined. This means that column header names and data types should be known during the design time.

On the other hand, MDX queries return a dataset that has the column names already pre-decided. Let's quickly review how the column names are pre-determined in MDX queries.

On the **COLUMNS** axis, the name of the measure will become the name of the column. For example, if we put these two measures on the **COLUMNS** axis, we will get two columns with the names, **Internet Sales Amount** and **Internet Gross Profit**.

```
[Measures].[Internet Sales Amount]  
[Measures].[Internet Gross Profit]
```

Please note that we are assuming that only measures will be put on the **COLUMNS** axis. Please refer to the *There is more...* section to see why.

On the **ROWS** axis, the name of the attribute from a dimension will become the name of the column. For example, if we put the **CROSSJOIN** of these two attributes from the **Product** and the **Date** dimension on the **ROWS** axis, we will get two columns with the names, **SubCategory** and **Date**.

```
[Product].[SubCategory].[SubCategory] *  
[Date].[Date].[Date]
```

In SSRS, if we use the user hierarchies **Product Categories** and **Calendar**, instead of the attributes, we will get the name of each level in the user hierarchy as the names of the columns. In addition to **SubCategory**, we will also get a column with the name **Category**, because **Category** is a level preceding **SubCategory** in the **Product Categories**; in addition to **Date**, we will also get four more columns with the names **Calendar Year**, **Calendar Semester**, **Calendar Quarter**, and **Month**, because they are the four levels above to the **Date** level in the **Calendar** hierarchy.

```
[Product].[Product Categories].[SubCategory] *  
[Date].[Calendar].[Date]
```

With this quick review of how reporting tools require report headers known in design time and how MDX queries simply use measure, attribute, or level names as header names, we come to realize that there is a need to create column aliases in MDX queries. A common scenario is when the cube is re-designed and measure, attribute, or level names are changed. In this scenario, migrating existing reports that are stuck with the old headers can be done by modifying the MDX queries to add column aliases.

In this recipe, we will look at ways to create column aliases in MDX queries so that we can control the headers in the results. We will also look at how to physically put data on the column in the report.

Getting ready

In this recipe, we will create an MDX query to answer this question: what are the top five postal codes that have the best online gross profit for the product sub-category Tires and Tubes in the United States in the year 2013? In SSMS, the result should be the same as the screenshot. It must show the year, date, the subcategory, state, city, postal code, **Internet Sales Amount**, and **Internet Gross Profit**. We are assuming that the cube has been re-designed and that the State was renamed to State–Province. We are migrating an existing report in which the header is State. We will choose the option to create a column alias in the MDX query so that we do not need to modify the existing report.

				State	Internet Sales Amount	Internet Gross Profit
CY 2013	October 29, 2013	Tires and Tubes	98225	Washington	\$101.55	\$63.57
CY 2013	August 4, 2013	Tires and Tubes	91950	Califomia	\$92.74	\$58.06
CY 2013	February 21, 2013	Tires and Tubes	94010	Califomia	\$82.27	\$51.50
CY 2013	August 10, 2013	Tires and Tubes	97005	Oregon	\$81.16	\$50.81
CY 2013	November 28, 2013	Tires and Tubes	90401	California	\$79.98	\$50.07

How to do it...

Start SQL Server Management Studio and connect to your SSAS 2016 instance. Click on the **New Query** button and check that the target database is Adventure Works DW 2016.

1. On COLUMNS, let's put these two measures:

```
[Measures].[Internet Sales Amount]  
[Measures].[Internet Gross Profit]
```

2. On ROWS, let's put the CROSSJOIN of these sets:

```
[Date].[Calendar Year].&[2013] *  
[Date].[Date].Members *  
DESCENDANTS({[Product].[Product Categories].[Subcategory].[Tires and  
Tubes]}) *  
DESCENDANTS([Customer].[Customer Geography].[Country].&[United  
States],  
[Customer].[Customer Geography].[Postal Code], SELF)
```

3. Let's wrap around the CROSSJOIN sets in a TOPCOUNT() function:

```
TopCount  
( set_expression,  
5,  
[Measures].[Internet Gross Profit] )
```

4. Let's use WITH MEMBER to create a query-scoped calculated measure. This should create a column alias, [State], for [State-Province]:

```
WITH MEMBER [Measures].[State] AS  
[Customer].[Customer  
Geography].CurrentMember.Parent.PARENT.Member_Caption
```

5. Add this column alias to the COLUMNS axis.

6. Here is the final query. Execute it in SSMS; you should have the same result as shown in the screenshot in the *Getting ready* section.

```
WITH MEMBER [Measures].[State] AS  
[Customer].[Customer  
Geography].CurrentMember.Parent.PARENT.Member_Caption  
SELECT  
{ [Measures].[State],  
[Measures].[Internet Sales Amount],  
[Measures].[Internet Gross Profit] } ON COLUMNS,
```

```
TopCount
(
{ [Date].[Calendar Year].&[2013] } *
[Date].[Date].[Date].Members *
DESCENDANTS({ [Product].[Product Categories].[Subcategory].[Tires and Tubes] }) *
DESCENDANTS([Customer].[Customer Geography].[Country].& [United States],
[Customer].[Customer Geography].[Postal Code], SELF),
5,
[Measures].[Internet Gross Profit]
) ON ROWS
FROM
[Adventure Works]
```

7. Optionally, when you have executed it in SSRS Query Designer's Design mode, you should have the same result as shown in the following screenshot:

Calendar Year	Date	Category	Subcategory	Country	State-Province	City	Postal Code	State	Internet Sales Amount	Internet Gross Profit
CY 2013	October 29, 2013	Accessories	Tires and Tubes	United States	Washington	Bellingham	98225	Washington	101.55	63.5701
CY 2013	August 4, 2013	Accessories	Tires and Tubes	United States	California	National City	91950	California	92.74	58.055
CY 2013	February 21, 2013	Accessories	Tires and Tubes	United States	California	Burlingame	94010	California	82.27	51.5009
CY 2013	August 10, 2013	Accessories	Tires and Tubes	United States	Oregon	Beaverton	97005	Oregon	81.16	50.806
CY 2013	November 28, 2013	Accessories	Tires and Tubes	United States	California	Santa Monica	90401	California	79.98	50.0674

How it works...

The first thing we've noticed is that there are more columns in SSRS than in SSMS. But the minimum requirement of reporting is met in both SSRS and SSMS. The following discussion is applicable to any reporting in general. However, the reporting shape expansion when using user hierarchies and the DESCENDANTS () function is applicable specifically to SSRS.

Based on the reporting requirement, we have used the following three parameters for the report:

```
[Date].[Calendar Year].&[2013]
[Product].[Product Categories].[Subcategory].[Tires and Tubes]
[Customer].[Customer Geography].[Country].&[United States]
```

For the two numeric headers, we directly put the following two measures on the COLUMNS axis:

```
[Measures].[Internet Sales Amount]
[Measures].[Internet Gross Profit]
```

Also notice that we are using CROSSJOIN to create the cross products of each set. The CROSSJOIN is the basic way to get data on the column in the results.

The following table shows where each report header is from.

Report Headers	From	
Calendar Year	ROWS	[Date].[Calendar Year].&[2013]
Date	ROWS	[Date].[Date].[Date].Members
Category, Subcategory	ROWS	DESCENDANTS({[Product].[Product Categories].[Subcategory].[Tires and Tubes]})
Country, State-Province, City, Postal Code	ROWS	DESCENDANTS([Customer].[Customer Geography].[Country].and [United States], [Customer].[Customer Geography].[Postal Code], SELF)
State	WITH MEMBER MEMBER COLUMNS	WITH MEMBER [Measures].[State] AS [Customer].[Customer Geography].CurrentMember.Parent.Parent.Member_Caption
Internet Sales Amount	COLUMNS	[Measures].[Internet Sales Amount]
Internet Gross Profit	COLUMNS	[Measures].[Internet Gross Profit]

The Calendar Year and Date are two attributes from the Date dimension. Both attribute names, Calendar Year and Date, have become two headers in the results.

The DESCENDANTS () function around the subcategory member [Tires and Tubes] without the optional flags gave two columns, Subcategory and Category, in the results. The DESCENDANTS () function around the country member [United States] with the flags of level Postal Code and SELF gave four columns, Country, State-Province, City, and Postal Code, in the results.

In order to have the header State in the result set, we have created a query-scoped calculated measure, [Measures]. [State], and have put it on the COLUMNS axis. Because State is two levels above Postal Code, we have used two Parent functions to navigate up from the CurrentMember of the Postal Code.

The CROSSJOIN operation returns the cross product of one or more sets. The CROSSJOIN operation is the fundamental way of getting the data point on the column in the results. If you use attribute hierarchies, each attribute will become a header in the results. If you use user hierarchies, each level, from the specified level and above, will become a header in the results. In the latter case, which we discussed in the introduction of this recipe, your report shape will be expanded from only one column to multiple columns.

The DESCENDANTS () function is another way of expanding the report shape.

There's more...

We have used the TOPCOUNT () function, which actually hid an issue with using the DESCENDANTS () function in reporting.

```
SELECT
    { [Measures].[Internet Sales Amount],
      [Measures].[Internet Gross Profit] } ON COLUMNS,
NON EMPTY
    DESCENDANTS({[Product].[Product Categories].[Subcategory].[Tires and
Tubes] })
    ON ROWS
FROM
    [Adventure Works]
```

Execute the preceding query in SSRS Query Designer's Design mode; you will get the following result:

Category	Subcategory	Product	Internet Sales Amount	Internet Gross Profit
Accessories	Tires and Tubes	(null)	245529.32	153700.7512
Accessories	Tires and Tubes	HL Mountain Tire	48860	30586.36
Accessories	Tires and Tubes	HL Road Tire	27970.8	17509.7208
Accessories	Tires and Tubes	LL Mountain Tire	21541.38	13484.8694
Accessories	Tires and Tubes	LL Road Tire	22435.56	14044.6188
Accessories	Tires and Tubes	ML Mountain Tire	34818.39	21796.2657
Accessories	Tires and Tubes	ML Road Tire	23140.74	14486.0662

Notice that not only has the report shape been expanded to include all three levels from the Product Categories hierarchy, the **Product** column also has a **(null)** row. This row represents the total of all the products. Unless you have intended to have the total row in the results, you might mistake the total row as an individual product member row. When two or more user hierarchies are used in this way, the results will soon become hard to read.

Using attribute hierarchies gives us precise control of the report shape. Using other ways, such as user hierarchies or the DESCENDANTS () function, helps us to easily expand the report shape, but care needs to be taken when handling the summary rows.

Other navigational functions such as Ascendants () can also expand the report shape by including all the levels in the header in the results. If you execute the following query in the SSRS's Query Editor in the Design Mode, you will see that all the levels, Group and Country and Region from the Sales Territory hierarchy, have become the headers in the results, and also that a total row has been included.

```
SELECT
    Measures.[Reseller Order Count] ON COLUMNS,
    Ascendants(
        [Sales Territory].[Sales Territory].[Northwest]
    ) ON ROWS
FROM
    [Adventure Works]
```

Group	Country	Region	Reseller Order Count
North America	United States	Northwest	536
North America	United States	(null)	2474
North America	(null)	(null)	3166
(null)	(null)	(null)	3796

Named set or DIMENSION PROPERTIES has no effect in the shape of the reports

To be clear, creating column aliases is about controlling the column header names in results. This is different to using aliases inside MDX queries. In, previous recipe, *Removing empty rows*, we used WITH SET to create a set alias, [Profit]:

```
WITH SET [Profit] AS
{ [Measures].[Internet Gross Profit],
  [Measures].[Reseller Gross Profit],
  [Measures].[Gross Profit]
}
```

This set alias will not change the column header names in results. If we put [Profit] on COLUMNS, the column headers in the results will still be Internet Gross Profit, Reseller Gross Profit, and Gross Profit.

Although a query-scoped, calculated set, or a named set defined in the MDX script can create a set alias for reuse in an MDX query, it cannot change the headers in results.

The DIMENSION PROPERTIES clause provides additional data, but cannot cause the properties to display in the pivot result; therefore, it has no effect in the shape of the reports either.

Creating a column alias in MDX queries can mean data duplication

Renaming measures and attributes in a cube is common when the cube is re-designed. To migrate your existing reports, you can choose to create column aliases in the reporting tool or in your MDX queries. A reporting tool such as SSRS has the capability to create column aliases. In this case, depending on your preferences, you might choose to do it in the reporting tool or in the MDX queries. Since your cube is re-designed, and you are rewriting most likely your MDX query anyway, creating column aliases in MDX queries might be more productive.

Creating a column alias is a must with role-playing dimensions

Occasionally, we might end up having the same column name from different hierarchies. The Date dimension, which has a role-playing Shift Date dimension, is a good example. If we put the CROSSJOIN of these two dimensions Date and Shift Date on the ROWS axis, we will get the same header, Date, for both the order date and the shift date. In this case, we must create column aliases in MDX queries to distinguish them.

```
[Date].[Date].[Date] *
[Ship Date].[Date].[Date]
```

Avoiding using the NON EMPTY keyword on the COLUMNS axis

When pulling data from SSAS using MDX queries to destinations such as frontend reporting tools or SQL tables, we should consider removing the NON EMPTY keyword on COLUMNS.

When there is no data in the result set, the NON EMPTY keyword on COLUMNS will not return any columns. You will get an *object has no columns* type of error because the destination of either a pre-designed report or an SQL table expects the columns in the results.

When would an MDX query return no data and no columns in the result set? If we write our MDX query as shown in the following templates, and the measures are empty, then no data and no headers will return from the query. Dynamic reports can have unpredictable results due to the dynamic filtering of the data, and situations like the following can happen:

```
NON EMPTY {measures} ON COLUMNS + NON EMPTY ({set_expression}) ON ROWS  
  
NON EMPTY {measures} ON COLUMNS + NONEMPTY ({set_expression1},  
{set_expression2}) ON ROWS
```

Unless you truly want the reporting or the process to fail, consider removing the NON EMPTY keyword from the COLUMNS axis.

Removing the NON EMPTY keyword from the COLUMNS axis will allow the MDX to return the columns even when the query contains no data.

Query Editor in SSRS only allowing measures dimension in the COLUMNS

In the introduction of this recipe, we made an assumption that only measures will be put on the COLUMNS axis. This is because in **SSRS**, the Query Editor (and the graphical Query Designer) expects the MDX queries:

1. To not have CROSSJOIN in the COLUMNS (or 0-axis).
2. And to only have the Measures dimension in the COLUMNS (or 0-axis).

If you are using a third-party frontend reporting tool, it's important to understand the restrictions the tool places on how the MDX queries should be written.

A few more words...

Having said so much about creating column aliases in MDX queries, it is also important to understand that creating column aliases in MDX queries is not the same as it is in SQL. Creating column aliases in MDX queries can mean data duplication. This might not be the best choice, especially with too much data duplication. When designing reports, consideration should be given to the most efficient way in terms of aligning the attribute or level names in SSAS, with the headers in the results.

The important message to take away from this recipe is that when creating reports with frontend reporting tools, care must be taken when handling the totals row and controlling the headers in the results. It is also important to pay attention to whether the `ALL` member is included in each set.

See also

- The *Concise Reporting* recipe in Chapter 4 has some examples of the `DESCENDANTS()` function.
- The *Getting the summary* recipe is relevant. It shows how the `VisualTotal()` function can be used to get the total row from the visual items in the report without adding more headers to the report, and therefore without expanding the report shape.

Sorting data by dimensions

There are usually two types of sorting requirements in reporting: one is to sort by numeric measures and the other is to sort by dimension members alphabetically.

Data from SSAS is naturally sorted by attributes in dimensions. Members in an attribute can be sorted by its own key or name value or sorted by another attribute's key or name value. The two properties that are related to member sorting are `OrderBy` and `OrderByAttribute`.

For example, if we put all members from the Date attribute on the ROWS axis, the results will already be sorted in ascending order of the date. This is because the Date attribute is sorted by its key value in the cube.

```
[Date]. [Date]. [Date].MEMBERS
```

If we CROSSJOIN multiple sets, as shown in the following code snippet, the result will be sorted in ascending date order, then by customer name, and then by subcategory. In this case, the position of the set matters. The sorting order will be from left to right in ascending order.

```
[Date]. [Date]. [Date].MEMBERS *
[Customer]. [Customer]. [Customer] *
[Product]. [Subcategory]. [Subcategory]
```

Because SSAS has taken care of the sorting, no explicit sorting is needed in MDX queries in most situations.

However, there are a few cases where explicit sorting is needed. Let's look at two default sorting behaviors in SSAS first.

By default, members in attributes are sorted in ascending order. This default behavior sometime needs to be changed to descending order.

By default, when a user hierarchy is used instead of an attribute hierarchy, the data is sorted from the top level to the lower level. If we use the user hierarchy Product Categories, the data will be sorted by Category and then by Subcategory. When Category is not even shown in the results, this default behavior can be very confusing.

```
[Product]. [ Product Categories]. [Subcategory]
```

This default behavior can also be altered so that we bypass the Category level, and directly sort by the Subcategory.

Getting ready

It is a very common reporting requirement to compare data across several months. To create a dynamic report, we will need to create a picklist to allow users to select any month. We will retrieve all the months from the Date dimension. It also makes sense to display the months in descending order. In this recipe, we will write a query to create a picklist for months and sort it in descending order. The following screenshot shows what we want to achieve:

We will start from this simple query that displays all the months and their unique name values:

```
WITH MEMBER [Measures].[ParameterValue] AS
    [Date].[Calendar].CurrentMember.uniquename

SELECT
    { [Measures].[ParameterValue] } ON COLUMNS,
    [Date].[Calendar].[Month].MEMBERS
    ON ROWS
FROM
    [Adventure Works]
```

We used the `WITH` clause to create a column alias `[ParameterValue]` to show each month's unique name value. This will be the parameter value we can pass to a parameterized MDX query. The result will have two headers, **ParameterValue** and **Month**, as shown in the following screenshot:

Month	ParameterValue
January 2005	[Date].[Calendar].[Month].&[2005]&[1]
February 2005	[Date].[Calendar].[Month].&[2005]&[2]
March 2005	[Date].[Calendar].[Month].&[2005]&[3]
April 2005	[Date].[Calendar].[Month].&[2005]&[4]
May 2005	[Date].[Calendar].[Month].&[2005]&[5]
June 2005	[Date].[Calendar].[Month].&[2005]&[6]
July 2005	[Date].[Calendar].[Month].&[2005]&[7]
August 2005	[Date].[Calendar].[Month].&[2005]&[8]
September 2005	[Date].[Calendar].[Month].&[2005]&[9]
October 2005	[Date].[Calendar].[Month].&[2005]&[10]
November 2005	[Date].[Calendar].[Month].&[2005]&[11]
December 2005	[Date].[Calendar].[Month].&[2005]&[12]
January 2006	[Date].[Calendar].[Month].&[2006]&[1]
February 2006	[Date].[Calendar].[Month].&[2006]&[2]

The data is already sorted in ascending order. We will modify this query so that the picklist is explicitly sorted in descending order.

How to do it...

Start SQL Server Management Studio and connect to your SSAS 2016 instance. Click on the **New Query** button and check that the target database is Adventure Works DW 2016.

1. In the `WITH` clause, define a column alias `SortKey` using the `MemberValue` for the `CurrentMember` of the `Calendar` hierarchy.

```
MEMBER [Measures].[SortKey] AS  
[Date].[Calendar].CurrentMember.MemberValue
```

2. Add the column alias `SortKey` to the `COLUMNS` axis.

3. On ROWS, let's sort the set [Date]. [Calendar]. [Month]. MEMBERS by the [SortKey] in descending order:

```
ORDER (
    [Date].[Calendar].[Month].MEMBERS,
    [Measures].[SortKey],
    DESC)
```

4. Here is the final query. Execute it in SSMS; you should have the same result as shown in the following screenshot:

```
WITH MEMBER [Measures].[SortKey] AS
    [Date].[Calendar].CurrentMember.membervalue
MEMBER [Measures].[ParameterValue] AS
    [Date].[Calendar].CurrentMember.uniquename
SELECT
{ [Measures].[ParameterValue], [Measures].[SortKey] } ON COLUMNS,
ORDER (
    [Date].[Calendar].[Month].MEMBERS,
    [Measures].[SortKey],
    DESC)
ON ROWS
FROM
[Adventure Works]
```

	ParameterValue	SortKey
December 2014	[Date].[Calendar].[Month]&[2014]&[12]	12/1/2014
November 2014	[Date].[Calendar].[Month]&[2014]&[11]	11/1/2014
October 2014	[Date].[Calendar].[Month]&[2014]&[10]	10/1/2014
September 2014	[Date].[Calendar].[Month]&[2014]&[9]	9/1/2014
August 2014	[Date].[Calendar].[Month]&[2014]&[8]	8/1/2014
July 2014	[Date].[Calendar].[Month]&[2014]&[7]	7/1/2014
June 2014	[Date].[Calendar].[Month]&[2014]&[6]	6/1/2014
May 2014	[Date].[Calendar].[Month]&[2014]&[5]	5/1/2014
April 2014	[Date].[Calendar].[Month]&[2014]&[4]	4/1/2014
March 2014	[Date].[Calendar].[Month]&[2014]&[3]	3/1/2014
February 2014	[Date].[Calendar].[Month]&[2014]&[2]	2/1/2014
January 2014	[Date].[Calendar].[Month]&[2014]&[1]	1/1/2014
December 2013	[Date].[Calendar].[Month]&[2013]&[12]	12/1/2013
November 2013	[Date].[Calendar].[Month]&[2013]&[11]	11/1/2013

5. Optionally, when executing it in SSRS Query Designer's Design mode, you should have the same result as shown in the following screenshot:

Calendar Year	Calendar Semester	Calendar Quarter	Month	ParameterValue	SortKey
CY 2014	H2 CY 2014	Q4 CY 2014	December 2014	[Date].[Calendar].[Month].&[2014]&[12]	12/1/2014 12:00:00 AM
CY 2014	H2 CY 2014	Q4 CY 2014	November 2014	[Date].[Calendar].[Month].&[2014]&[11]	11/1/2014 12:00:00 AM
CY 2014	H2 CY 2014	Q4 CY 2014	October 2014	[Date].[Calendar].[Month].&[2014]&[10]	10/1/2014 12:00:00 AM
CY 2014	H2 CY 2014	Q3 CY 2014	September 2014	[Date].[Calendar].[Month].&[2014]&[9]	9/1/2014 12:00:00 AM
CY 2014	H2 CY 2014	Q3 CY 2014	August 2014	[Date].[Calendar].[Month].&[2014]&[8]	8/1/2014 12:00:00 AM
CY 2014	H2 CY 2014	Q3 CY 2014	July 2014	[Date].[Calendar].[Month].&[2014]&[7]	7/1/2014 12:00:00 AM
CY 2014	H1 CY 2014	Q2 CY 2014	June 2014	[Date].[Calendar].[Month].&[2014]&[6]	6/1/2014 12:00:00 AM
CY 2014	H1 CY 2014	Q2 CY 2014	May 2014	[Date].[Calendar].[Month].&[2014]&[5]	5/1/2014 12:00:00 AM
CY 2014	H1 CY 2014	Q2 CY 2014	April 2014	[Date].[Calendar].[Month].&[2014]&[4]	4/1/2014 12:00:00 AM
CY 2014	H1 CY 2014	Q1 CY 2014	March 2014	[Date].[Calendar].[Month].&[2014]&[3]	3/1/2014 12:00:00 AM
CY 2014	H1 CY 2014	Q1 CY 2014	February 2014	[Date].[Calendar].[Month].&[2014]&[2]	2/1/2014 12:00:00 AM
CY 2014	H1 CY 2014	Q1 CY 2014	January 2014	[Date].[Calendar].[Month].&[2014]&[1]	1/1/2014 12:00:00 AM
CY 2013	H2 CY 2013	Q4 CY 2013	December 2013	[Date].[Calendar].[Month].&[2013]&[12]	12/1/2013 12:00:00 AM
CY 2013	H2 CY 2013	Q4 CY 2013	November 2013	[Date].[Calendar].[Month].&[2013]&[11]	11/1/2013 12:00:00 AM
CY 2013	H2 CY 2013	Q4 CY 2013	October 2013	[Date].[Calendar].[Month].&[2013]&[10]	10/1/2013 12:00:00 AM

How it works...

Let's start with the `Order()` function. It has two syntaxes:

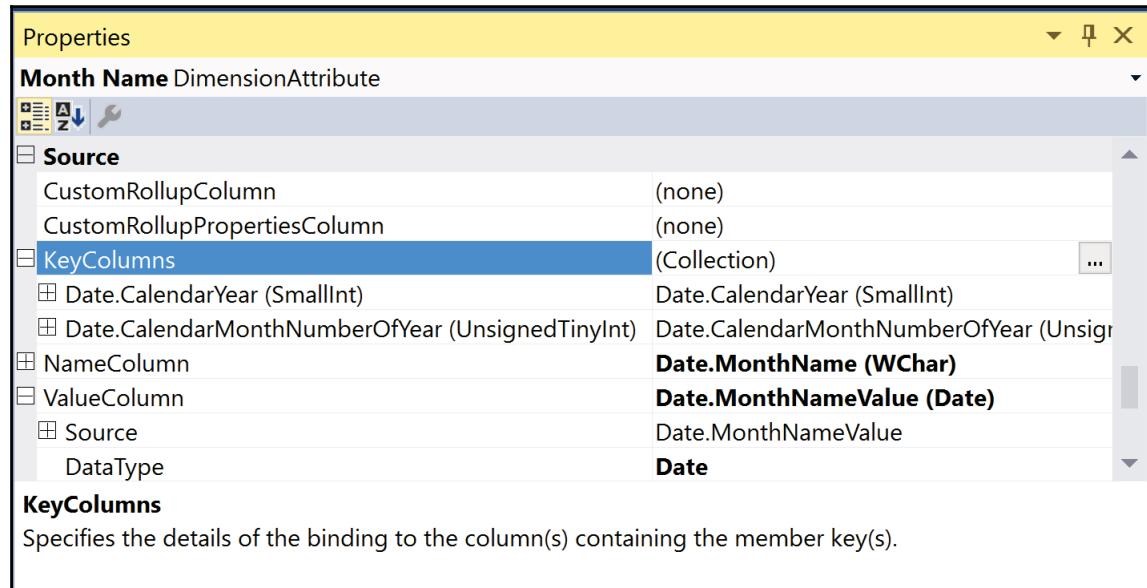

```
Order(Set_Expression, Numeric_Expression, Ordering_Option)
Order(Set_Expression, String_Expression, Ordering_Option)
```

The ordering option can be any of these: **ASC**, **DESC**, **BASC**, **BDESC**, with ASC for ascending, DESC for descending, and letter B standing for *break hierarchy*. The sorting is hierarchical when ASC or DESC is used or non-hierarchical when BASC or BDESC is used.

The `Order()` function is a very confusing function when a user hierarchy is used in the set, or when a string expression is used.

In the *There's more...* section, we will discuss the non-hierarchical sorting. Here, we are going to focus on the string expression syntax.

We wanted to sort the picklist in descending order of the months. Month is not a numeric expression in the Adventure Works cube. Let's go to the Adventure Works SSDT Visual Studio project and open the dimension designer for the Date dimension.

The Month Name attribute is the source of the Month level in the Calendar hierarchy. Its key is a composite key consisting of both the year and month number; the name column is the MonthName, which has a data type of string; and the value column is the MonthNameValue, which has a data type of Date. To sort the month correctly, we must sort by the date value of each month, not by the alphabetical order of the month name.

We have used the MemberValue function to get the MonthNameValue in the WITH clause:

```
MEMBER [Measures].[SortKey] AS
    [Date].[Calendar].CurrentMember.membervalue
```

But if the member value is showing as 12/1/2014 in SSMS, or 12/1/2014 12:00:00 AM in SSRS, how can we sort it correctly? It turns out that the displayed value is only the tool's own formatting of the date. The member value itself has a data type of Date, which is why we can use it for sorting.

To further understand that MonthNameValue has a data type of Date, you can go to the data source view of Adventure Works DW. You should see that MonthNameValue is defined as a named calculation:

```
CAST(
    CONVERT( CHAR(2), MonthNumberOfYear)
    + '/' + '1/' +
    CONVERT(CHAR(4), CalendarYear) AS DATE
)
```

You can try this SQL query in SSMS to see that the sorting by this MonthNameValue of Date type is correct.

```
SELECT DISTINCT
    CAST(
        CONVERT( CHAR(2), MonthNumberOfYear)
        + '/' + '1/' +
        CONVERT(CHAR(4), CalendarYear) AS DATE
    ) AS MonthNameValue
FROM [AdventureWorksDW2016].[dbo].[DimDate]
ORDER BY
    CAST(
        CONVERT( CHAR(2), MonthNumberOfYear)
        + '/' + '1/' +
        CONVERT(CHAR(4), CalendarYear) AS DATE
    ) DESC
```

MonthNameValue	
1	2014-12-01
2	2014-11-01
3	2014-10-01
4	2014-09-01
5	2014-08-01
6	2014-07-01
7	2014-06-01
8	2014-05-01
9	2014-04-01
10	2014-03-01

There's more...

We have used the `MemberValue` function to get `MonthNameValue`, which has a data type of `Date`. Using it to sort the month is a perfect choice.

There are two other ways to sort the months in descending order. Let's take a look at them.

Taking advantage of hierarchical sorting

When creating the picklist, we need the `ParameterValue` header. It turns out that we can use it to sort the months without the `SortKey`, that is, `MonthNameValue`.

```
WITH MEMBER [Measures].[ParameterValue] AS
    [Date].[Calendar].CurrentMember.uniquename

SELECT
    { [Measures].[ParameterValue] } ON COLUMNS,
    ORDER (
        [Date].[Calendar].[Month].MEMBERS,
        [Measures].[ParameterValue],
        DESC)
    ON ROWS
FROM
    [Adventure Works]
```

The result is shown in the following screenshot. The months are sorted correctly in descending order.

Calendar Year	Calendar Semester	Calendar Quarter	Month	ParameterValue
CY 2014	H2 CY 2014	Q4 CY 2014	December 2014	[Date].[Calendar].[Month].&[2014]&[12]
CY 2014	H2 CY 2014	Q4 CY 2014	November 2014	[Date].[Calendar].[Month].&[2014]&[11]
CY 2014	H2 CY 2014	Q4 CY 2014	October 2014	[Date].[Calendar].[Month].&[2014]&[10]
CY 2014	H2 CY 2014	Q3 CY 2014	September 2014	[Date].[Calendar].[Month].&[2014]&[9]
CY 2014	H2 CY 2014	Q3 CY 2014	August 2014	[Date].[Calendar].[Month].&[2014]&[8]
CY 2014	H2 CY 2014	Q3 CY 2014	July 2014	[Date].[Calendar].[Month].&[2014]&[7]
CY 2014	H1 CY 2014	Q2 CY 2014	June 2014	[Date].[Calendar].[Month].&[2014]&[6]
CY 2014	H1 CY 2014	Q2 CY 2014	May 2014	[Date].[Calendar].[Month].&[2014]&[5]
CY 2014	H1 CY 2014	Q2 CY 2014	April 2014	[Date].[Calendar].[Month].&[2014]&[4]
CY 2014	H1 CY 2014	Q1 CY 2014	March 2014	[Date].[Calendar].[Month].&[2014]&[3]
CY 2014	H1 CY 2014	Q1 CY 2014	February 2014	[Date].[Calendar].[Month].&[2014]&[2]
CY 2014	H1 CY 2014	Q1 CY 2014	January 2014	[Date].[Calendar].[Month].&[2014]&[1]
CY 2013	H2 CY 2013	Q4 CY 2013	December 2013	[Date].[Calendar].[Month].&[2013]&[12]
CY 2013	H2 CY 2013	Q4 CY 2013	November 2013	[Date].[Calendar].[Month].&[2013]&[11]
CY 2012	H2 CY 2012	Q4 CY 2012	October 2012	[Date].[Calendar].[Month].&[2012]&[10]

From the result, we can see that the sorting is done in a hierarchical way because we used the user hierarchy `Calendar`. The sorting is exactly what we want to achieve.

Using the Date type to sort in a non-hierarchical way

On the other hand, if we use attribute hierarchy `Month Name` instead of the user hierarchy `Calendar`, then we must be careful. We can no longer use `UniqueName` to sort; instead, we must use `MemberValue` to sort.

```
WITH MEMBER [Measures].[SortKey] AS  
    [Date].[Month Name].CurrentMember.membervalue  
MEMBER [Measures].[ParameterValue] AS  
    [Date].[Month Name].CurrentMember.uniqueName  
SELECT  
    { [Measures].[ParameterValue], [Measures].[SortKey] } ON COLUMNS,  
    ORDER (  
        [Date].[Month Name].Children,  
        [Measures].[ParameterValue],  
        DESC)  
    ON ROWS  
FROM  
    [Adventure Works]
```

The preceding query will not sort the months in descending order correctly. Notice that `&[9]` comes before `&[12]`, because 9 is bigger than 12 as a string type.

	ParameterValue	SortKey
September 2014	[Date].[Month Name]&[2014]&[9]	9/1/2014
August 2014	[Date].[Month Name]&[2014]&[8]	8/1/2014
July 2014	[Date].[Month Name]&[2014]&[7]	7/1/2014
June 2014	[Date].[Month Name]&[2014]&[6]	6/1/2014
May 2014	[Date].[Month Name]&[2014]&[5]	5/1/2014
April 2014	[Date].[Month Name]&[2014]&[4]	4/1/2014
March 2014	[Date].[Month Name]&[2014]&[3]	3/1/2014
February 2014	[Date].[Month Name]&[2014]&[2]	2/1/2014
December 2014	[Date].[Month Name]&[2014]&[12]	12/1/2014
November 2014	[Date].[Month Name]&[2014]&[11]	11/1/2014
October 2014	[Date].[Month Name]&[2014]&[10]	10/1/2014

Simply use SortKey to replace ParameterValue, and the sorting will be corrected.

```
WITH MEMBER [Measures].[SortKey] AS  
    [Date].[Month Name].CurrentMember.membervalue  
MEMBER [Measures].[ParameterValue] AS  
    [Date].[Month Name].CurrentMember.uniquename  
SELECT  
    { [Measures].[ParameterValue], [Measures].[SortKey] } ON COLUMNS,  
    ORDER (   
        [Date].[Month Name].Children,  
        [Measures].[SortKey],  
        DESC)  
    ON ROWS  
FROM  
    [Adventure Works]
```

“Break hierarchy” – sorting a set in a non-hierarchical way

The ORDER() function can be very confusing when a user hierarchy is used.

Let's look at this example of sorting the set [Date].[Calendar].[Month].MEMBERS with a numeric measure [Internet Sales Amount] and a sorting flag of DESC.

```
SELECT  
    { [Measures].[Internet Sales Amount] } ON COLUMNS,  
    ORDER (   
        [Date].[Calendar].[Month].MEMBERS,  
        [Measures].[Internet Sales Amount],  
        DESC)  
    ON ROWS  
FROM  
    [Adventure Works]
```

The result is shown in the following screenshot in SSMS. The ordering isn't exactly correct. The internet sales number for **June 2013** is obviously out of order.

	Internet Sales...
December 2013	\$1,874,360.29
November 2013	\$1,780,920.06
October 2013	\$1,673,293.41
August 2013	\$1,551,065.56
September 2013	\$1,447,495.69
July 2013	\$1,371,675.81
June 2013	\$1,643,177.78
May 2013	\$1,284,592.93
April 2013	\$1,046,022.77
March 2013	\$1,049,907.39
January 2013	\$857,689.91

The reason is unclear until you execute the previous query in the SSRS Query Editor's Design Mode. The result not only has the **Month** header, but it also has all the levels preceding **Month** in the **Calendar** user hierarchy. **June 2013** is under **Q2 CY 2013**, which should be displayed after **Q3 CY 2013** in descending order of the hierarchy. Therefore, it will not show after **October 2013**.

Calendar Year	Calendar Semester	Calendar Quarter	Month	Internet Sales Amount
CY 2013	H2 CY 2013	Q4 CY 2013	December 2013	1874360.29
CY 2013	H2 CY 2013	Q4 CY 2013	November 2013	1780920.06
CY 2013	H2 CY 2013	Q4 CY 2013	October 2013	1673293.41
CY 2013	H2 CY 2013	Q3 CY 2013	August 2013	1551065.56
CY 2013	H2 CY 2013	Q3 CY 2013	September 2013	1447495.69
CY 2013	H2 CY 2013	Q3 CY 2013	July 2013	1371675.81
CY 2013	H1 CY 2013	Q2 CY 2013	June 2013	1643177.78
CY 2013	H1 CY 2013	Q2 CY 2013	May 2013	1284592.93
CY 2013	H1 CY 2013	Q2 CY 2013	April 2013	1046022.77
CY 2013	H1 CY 2013	Q1 CY 2013	March 2013	1049907.39
CY 2013	H1 CY 2013	Q1 CY 2013	January 2013	857689.91
CY 2013	H1 CY 2013	Q1 CY 2013	February 2013	771348.74
CY 2011	H2 CY 2011	Q4 CY 2011	October 2011	708208.0032
CY 2011	H2 CY 2011	Q4 CY 2011	December 2011	669431.5031
CY 2011	H2 CY 2011	Q4 CY 2011	November 2011	669431.5031

This is when the *break hierarchy* comes into play. By using the BDESC flag, we are going to sort the set in a non-hierarchical way. Replacing the ordering part with the following code with the BDESC flag, the months will now be truly sorted by the Reseller Sales Amount in descending order in both SSMS and SSRS.

```
ORDER (
    [Date].[Calendar].[Month].MEMBERS,
    [Measures].[Internet Sales Amount],
    BDESC)
ON ROWS
```

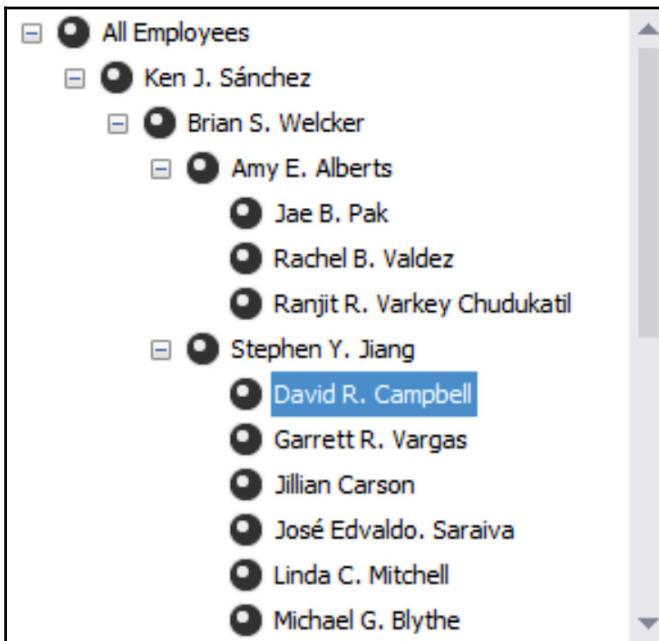

You might also need to *break hierarchy* when working with parent-child dimensions. In Adventure Works DW, the Employee dimension is a parent-child dimension.

```
SELECT
    [Measures].[Reseller Sales Amount] ON COLUMNS,
    NON EMPTY
    DESCENDANTS([Employee].[Employees].[Employee Level 02],,LEAVES)
    ON ROWS
FROM
    [Adventure Works]
```

The previous query's result is shown in the following screenshot:

	Reseller Sales Amount
Jae B. Pak	\$8,503,338.65
Rachel B. Valdez	\$1,790,640.23
Ranjit R. Varkey Chudukatil	\$4,509,888.93
David R. Campbell	\$3,729,945.35
Garnett R. Vargas	\$3,609,447.22
Jillian Carson	\$10,065,803.54
José Edvaldo. Saraiva	\$5,926,418.36
Linda C. Mitchell	\$10,367,007.43
Michael G. Blythe	\$9,293,903.01
Pamela O. Ansman-Wolfe	\$3,325,102.60

The result does not seem to be sorted in any noticeable order, until you realize that the Employee hierarchy in the Employee dimension is a parent-child hierarchy.

David R. Campbell comes after **Jae B. Pak** because his manager **Stephen Y. Jiang** comes after **Amy E. Alberts**.

Using the ORDER() function with the [Employee].[Employees].MemberValue and BASC flag to *break hierarchy* will sort the employees in alphabetical order.

Here is the complete query:

```
SELECT  
    [Measures].[Reseller Sales Amount] ON COLUMNS,  
    NON EMPTY  
    ORDER (  
        DESCENDANTS([Employee].[Employees].[Employee Level 02],,LEAVES),  
        [Employee].[Employees].MemberValue,  
        BASC)  
    ON ROWS  
FROM  
    [Adventure Works]
```

Sorting can be done in the frontend reporting tool

This recipe discusses sorting by dimension members in reporting. However, sorting does not need to be done in MDX queries. Sorting can be done in the frontend reporting tool. You might not want to do sorting in an MDX query when the sorting requirement is complex and involves grouping at many levels, or when you need to provide interactive sorting by users in the front-end reporting tool.

Business Analyses

In this chapter, we will cover the following recipes:

- Forecasting using linear regression
- Forecasting using periodic cycles
- Allocating non-allocated company expenses to departments
- Analyzing the fluctuation of customers
- Implementing the ABC analysis

Introduction

In the first part of this chapter, we will focus on how to perform some of the typical business analyses such as forecasting, allocating values, and calculating the number of days from the last sale date.

To forecast future business, we frequently use linear regression to calculate the trend line, which can tell us how the business will likely be doing in the future, if everything continues in the same direction. Many businesses have a cyclic behavior, and the cycle period can be a year, a month, a week, and so on. If we can calculate the values for the next cycle using the trend line from a previous cycle, we will have a better approximation of the future results than we would be able to get from simply using a linear trend. We will learn how to do forecasting using both linear regression and periodic cycles.

Businesses can have unallocated expenses, such as **operating expenses** that are charged to corporates, but not allocated to individual departments. The key to allocating these expenses to individual departments is to calculate a percentage of an expense value of each member department against the aggregate of all the other sibling departments. This percentage can then be used to spread the unallocated expenses to individual departments. In the third recipe in this chapter, we will learn the allocation scheme to calculate the allocation percentages (ratios) and to effectively allocate any measures to any coordinate.

The second half of this chapter shows how to determine the behavior of individual members. These are the last two recipes.

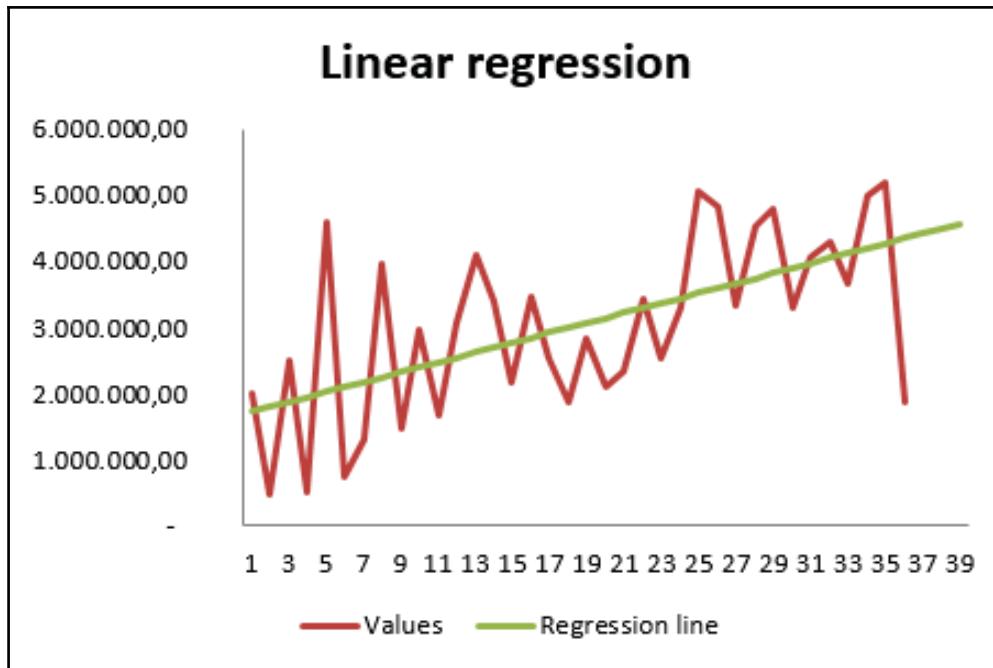

One recipe performs analysis on customers to determine new, returning (loyal), and lost customers. It illustrates an approach that becomes useful when we need to track fluctuations in periods.

In the last recipe, we turn our focus from customer analysis to item grouping. ABC analysis is a method of identifying and classifying items, based on their contribution, into three groups: A, B, and C. In our example, we will use a 30/50/20 ratio as an extension to the 80-20 rule, putting the top 80 percent of product members into two segments of 30 percent and 50 percent.

Let's start!

Forecasting using linear regression

This recipe illustrates the method of estimating the future values based on a linear trend. The linear trend is calculated using the least-square distance, a statistical method of determining the line that fits the best through the set of values in the chart, as displayed in the following figure:

Mathematically, linear regression can be represented by a regression line, $y = ax + b$, where y is the value of the y -intercept for a value of x .

Linear regression is often used in a way that x is a period and y is the value in a particular time, for example, a month.

Most importantly, the regression line is used to forecast values outside the initial period. For example, we can use a period of 60 months and forecast the value for each of the following 12 months.

This recipe shows how to estimate the values of the two months after the period of 36 months that were used in the calculation. The screenshot you saw in the introduction of this recipe shows the regression line and forecasted values for those two months.

Getting ready

Start SQL Server Management Studio and connect to your SSAS 2016 instance. Click on the **New Query** button and check that the target database is Adventure Works DW 2016.

In this example, we're going to use the `Date` dimension. Here's the query we'll start from:

```
SELECT
    { [Measures].[Sales Amount] } ON 0,
    { [Date].[Calendar].[Month].MEMBERS } ON 1
FROM
    [Adventure Works]
```

Once executed, the query returns 120 months, from January 2005 to December 2014, with no gaps in between. However, not every month has a sales amount. The first month with data is December 2010, and the last month with data is January 2014.

The `Date` dimension in the Adventure Works DW 2016 database follows the best practice guideline, which says that all months should be consecutive with no holes inside the year. If you are working on earlier versions of the Adventure Works database, such as the 2008R2 database, you might have noticed that this best practice guideline is not strictly followed. The month starts from July 2005 to August 2008, with one extra month in the year 2010 (November) as the next member in the hierarchy, which is in fact more than two years apart.

Our task will be to forecast the sales amount beyond those three years, from January 2014 to December 2014, all based on the sales of the three previous calendar years. We are also going to remove periods before January 2011 from our analysis, as there is no significant sales data there or no data at all.

On the other side, January 2014 has data, but only a portion of it (it becomes clear by comparing it with previous monthly values or by analyzing the cube by dates). Therefore, we are also going to forecast its sales, and we'll do so by not including its data in the calculation. In other words, we'll use only three full years of data for our input.

As explained in the introduction, we'll use the linear regression method in this recipe, while the next recipe will show you how to do the same using another approach—the method of periodic cycles.

How to do it...

Follow these steps to add the linear regression code to your MDX:

1. Add the `WITH` part of the query.
2. Create a named set, `Full Period`. The definition for this set should be the range of months from January 2011 to December 2014.

```
{  
    [Date].[Calendar].[Month].&[2011]&[1] :  
    [Date].[Calendar].[Month].&[2014]&[12]  
}
```

3. Create a named set, `Input Period`. The definition for this set should be the range of months from January 2011 to December 2013.

```
{  
    [Date].[Calendar].[Month].&[2011]&[1] :  
    [Date].[Calendar].[Month].&[2013]&[12]  
}
```

4. Create several calculated members. The first, `Input X`, is a measure that determines the rank of the current calendar member in the named set `Input Period`.
5. The second, `Input Y`, is a measure that is an alias for the `Sales Amount` measure.
6. The third, `Output X`, is a measure like `Input X`, only this time we're determining the rank in the first set, `Full Period`.
7. Finally, the fourth calculated member, `Forecast`, will be a measure that contains the formula, which combines all the previous calculated members and sets and calculates the regression line using the `LinRegPoint()` function:

```
LinRegPoint(  
    [Measures].[Output X],  
    [Input Period],  
    [Measures].[Input Y],  
    [Measures].[Input X]  
)
```

8. Specify `$#,##0.00` as a format string of the `Forecast` measure.
9. Add the `Forecast` measure on axis 0, next to the `Sales Amount` measure.

10. Replace the set on axis 1 with the named set `Full Period` because we don't want to see previous years with no data in them.
11. Verify that your query looks like the following one. Execute it:

```
WITH
SET [Full Period] AS
{ [Date].[Calendar].[Month].&[2011]&[1] :
  [Date].[Calendar].[Month].&[2014]&[12] }
SET [Input Period] AS
{ [Date].[Calendar].[Month].&[2011]&[1] :
  [Date].[Calendar].[Month].&[2013]&[12] }
MEMBER [Measures].[Input X] AS
  Rank( [Date].[Calendar].CurrentMember,
        [Input Period] )
MEMBER [Measures].[Input Y] AS
  [Measures].[Sales Amount]
MEMBER [Measures].[Output X] AS
  Rank( [Date].[Calendar].CurrentMember,
        [Full Period] )
MEMBER [Measures].[Forecast] AS // = Output Y
  LinRegPoint(
    [Measures].[Output X],
    [Input Period],
    [Measures].[Input Y],
    [Measures].[Input X]
  )
  , FORMAT_STRING = '$#,##0.00'
SELECT
{ [Measures].[Sales Amount],
  [Measures].[Forecast] } ON 0,
{ [Full Period] } ON 1
FROM
[Adventure Works]
```

12. Verify that the result matches the following screenshot. The highlighted cells contain the forecasted values.

	Sales Amount	Forecast
January 2013	\$5,070,661.42	\$3,521,033.16
February 2013	\$4,818,922.78	\$3,595,932.15
March 2013	\$3,332,023.27	\$3,670,831.14
April 2013	\$4,529,184.17	\$3,745,730.13
May 2013	\$4,795,541.66	\$3,820,629.12
June 2013	\$3,305,725.10	\$3,895,528.11
July 2013	\$4,070,976.60	\$3,970,427.10
August 2013	\$4,289,719.18	\$4,045,326.09
September 2013	\$3,654,220.91	\$4,120,225.08
October 2013	\$4,987,894.19	\$4,195,124.07
November 2013	\$5,197,154.91	\$4,270,023.06
December 2013	\$1,874,360.29	\$4,344,922.05
January 2014	\$45,694.72	\$4,419,821.04
February 2014	(null)	\$4,494,720.03
March 2014	(null)	\$4,569,619.02
April 2014	(null)	\$4,644,518.01
May 2014	(null)	\$4,719,417.00
June 2014	(null)	\$4,794,315.99
July 2014	(null)	\$4,869,214.98
August 2014	(null)	\$4,944,113.97
September 2014	(null)	\$5,019,012.96
October 2014	(null)	\$5,093,911.95
November 2014	(null)	\$5,168,810.95
December 2014	(null)	\$5,243,709.94

How it works...

In this example, we've used a few more calculated members and sets than necessary. We've defined two named sets and three calculated members before we came to the main part of the query: the fourth calculated member, which contains the formula for forecasting values based on the linear trend. We did this extra bit of work to have a simple and easy-to-memorize expression for the otherwise complicated `LinRegPoint()` function, and because not all years had data.

The `LinRegPoint()` function has four parameters. Names used in this example suggest what these parameters represent. The key to using this function is to provide these four parameters correctly. So, let's repeat the function and the four parameters from our previous query:

```
LinRegPoint(  
    [Measures].[Output X],  
    [Input Period],  
    [Measures].[Input Y],  
    [Measures].[Input X]  
)
```

As the names suggest, the last three parameters (`Input Period`, `Input X`, and `Input Y`) are all inputs used to determine the regression line $y = a \cdot x + b$. Here, we've specified a set of members (the January 2011–December 2013 period), their ordinal positions in that set (values 1 – 36 obtained using the `Rank()` function on that period), and their corresponding values (measuring the sales amount). We've prefixed all of them with `Input` to emphasize that these parameters are used as the input for the calculation of the regression line.

Once the regression line is calculated internally, it is used in combination with the first parameter, `Output X`. This two-step process is a composition of functions where the result of the inner one is used as the argument in the outer one. This is what makes the `LinRegPoint()` function difficult to understand and remember. Hopefully, by making a distinction between parameters, that is, prefixing them as input and output parameters, the function becomes less difficult to understand.

Here is the calculation we used for `Input X`. Notice that for input, we have included only the periods that have a sale amount.

```
Rank( [Date].[Calendar].CurrentMember, [Input Period] )
```

Now starts the second phase, the invisible outer function.

The first parameter (`Output X`) is used to specify the ordinal position of the member that we want to calculate the value for. Here is the calculation for `Output X`:

```
Rank( [Date].[Calendar].CurrentMember, [Full Period] )
```

Notice that we've used `[Full Period]`, which is a different set than what we used for the parameter `Input X`, because our primary need was to get the value for members whose positions are beyond December 2013.

Notice also that the measure `Forecast` represents the `Output Y` value which was hinted at in the code. In other words, for a given regression line (based on the `Input` parameters), we have calculated the y value for any given x , including, but not limited, to the initial set of members. That was step two in the evaluation of the `LinRegPoint()` function.

There's more...

The `LinRegPoint()` is not the only MDX function which can be used to calculate the values based on the regression line. Remember we said this function evaluates in a two-step process. The result of the inner step is not one but two numbers. One is the slope; the other the intercept. In other words, the a and b in the $y = a \cdot x + b$ equation.

You might feel more comfortable using the slope (a) and the intercept (b) to forecast a value. If that's the case, then here's the add-on to the previous example.

Add this part of the code in the previous query, and then add those three calculated members on axis 0 and run the query:

```
MEMBER [Measures].[Slope] AS // = a
    LinRegSlope(
        [Input Period],
        [Measures].[Input Y],
        [Measures].[Input X]
    )
    , FORMAT_STRING = '#,#'
MEMBER [Measures].[Intercept] AS // = b
    LinRegIntercept(
        [Input Period],
        [Measures].[Input Y],
        [Measures].[Input X]
    )
    , FORMAT_STRING = '#,#'
MEMBER [Measures].[Verify y = a * x + b] AS
    [Measures].[Slope] * [Measures].[Output X] +
    [Measures].[Intercept]
// y = a * x + b
    , FORMAT_STRING = '$#,##0.00'
```

The result will look like the following screenshot:

	Sales Amount	Forecast	Slope	Intercept	Verify $y = a * x + b$
January 2013	\$5,070,661.42	\$3,521,033.16	74,899	1,648,558	\$3,521,033.16
February 2013	\$4,818,922.78	\$3,595,932.15	74,899	1,648,558	\$3,595,932.15
March 2013	\$3,332,023.27	\$3,670,831.14	74,899	1,648,558	\$3,670,831.14
April 2013	\$4,529,184.17	\$3,745,730.13	74,899	1,648,558	\$3,745,730.13
May 2013	\$4,795,541.66	\$3,820,629.12	74,899	1,648,558	\$3,820,629.12
June 2013	\$3,305,725.10	\$3,895,528.11	74,899	1,648,558	\$3,895,528.11
July 2013	\$4,070,976.60	\$3,970,427.10	74,899	1,648,558	\$3,970,427.10
August 2013	\$4,289,719.18	\$4,045,326.09	74,899	1,648,558	\$4,045,326.09
September 2013	\$3,654,220.91	\$4,120,225.08	74,899	1,648,558	\$4,120,225.08
October 2013	\$4,987,894.19	\$4,195,124.07	74,899	1,648,558	\$4,195,124.07
November 2013	\$5,197,154.91	\$4,270,023.06	74,899	1,648,558	\$4,270,023.06
December 2013	\$1,874,360.29	\$4,344,922.05	74,899	1,648,558	\$4,344,922.05
January 2014	\$45,694.72	\$4,419,821.04	74,899	1,648,558	\$4,419,821.04
February 2014	(null)	\$4,494,720.03	74,899	1,648,558	\$4,494,720.03
March 2014	(null)	\$4,569,619.02	74,899	1,648,558	\$4,569,619.02
April 2014	(null)	\$4,644,518.01	74,899	1,648,558	\$4,644,518.01
May 2014	(null)	\$4,719,417.00	74,899	1,648,558	\$4,719,417.00
June 2014	(null)	\$4,794,315.99	74,899	1,648,558	\$4,794,315.99
July 2014	(null)	\$4,869,214.98	74,899	1,648,558	\$4,869,214.98
August 2014	(null)	\$4,944,113.97	74,899	1,648,558	\$4,944,113.97
September 2014	(null)	\$5,019,012.96	74,899	1,648,558	\$5,019,012.96
October 2014	(null)	\$5,093,911.95	74,899	1,648,558	\$5,093,911.95
November 2014	(null)	\$5,168,810.95	74,899	1,648,558	\$5,168,810.95
December 2014	(null)	\$5,243,709.94	74,899	1,648,558	\$5,243,709.94

The three extra measures were the Slope, Intercept, and Verify $y = a * x + b$ measures. The first two were defined using the `LinRegSlope()` and `LinRegIntercept()` functions, respectively. The same last three parameters were used here as in the `LinRegPoint()` function. What `LinRegPoint()` does extra is that it takes it one step further and combines those two values with an additional parameter to calculate the final y .

From the previous screenshot, it is clear that `LinRegSlope()` and `LinRegIntercept()` can be used instead of the `LinRegPoint()` function, as the values are exactly the same. All it takes is to combine them in the equation $y = a * x + b$. Therefore, it is up to you to choose the preferred way for you to forecast the value based on the regression line.

Tips and tricks

The `Rank()` function is used to determine the ordinal position of a member in a set. Here, we've used it twice: to calculate the position of members in the `Input Period` set and to calculate the position of members in the `Full Period` set.

The `Rank()` function performs better if we extract the set used as the second argument and define it as a separate named set, which we did. This is because in that case the set is evaluated only once and not repeatedly for each cell.

Where to find more information

- The *Forecasting using periodic cycles* recipe covers a similar topic

Forecasting using periodic cycles

Linear trend, covered in the recipe *Forecasting using linear regression*, is just an overview of how the business is going. The regression line serves us merely as an indicator of where we will be in the future if everything continues in the same way. What it doesn't tell us, at least not well enough, is what the individual values on that path will be. The values that method returns are too simplified, too imprecise.

Of course, there are other ways of forecasting the future values, such as by using polynomial curves or similar, which, generally speaking, will fit better to the shape of achieved business values and therefore represent future values more precisely. However, we won't make an example using them; we will use something simple but effective instead.

What is characteristic of many businesses is that events tend to repeat themselves after some time. In other words, many of them have a cyclic behavior – whether that period is a year, a month, a week, a day, or whatever.

The simplification can be summarized like this: there's an envelope of events taking place during a cycle and there is a linear trend that says how much better or worse the next period is going to be compared to the previous one. When we say “the envelope”, we mean a shape of events and their values. For example, there might be a spike in the curve in Spring/Autumn when people buy shoes, there might be a spike in activity at the end of the month when people need to finish their reports, there might be a spike in the middle of the week because people are more business-focused in that part of the week, or there might even be a spike in the early morning or late afternoon because that's when people travel to and from work. All in all, things are not flat, and moreover, the shape of their non-flatness, more or less, looks the same in every cycle.

If we calculate the values for the next cycle using the trend line but keep the shape of the events in the cycle, we will have a better approximation and estimation of the future results than if we simply used a linear trend. It's not that we'll replace it with something else. No, we're just going to improve it by adjusting the stiffness of the regression line.

Getting ready

Open SQL Server Data Tools (SSDT) and then open the Adventure Works DW 2016 solution. Double-click on the **Adventure Works** cube and go to the **Calculations** tab. Choose **Script View**. Position the cursor at the end of the script where you'll create a calculated measure, `Sales`, `null`, by default, and then scope that measure so that only the values from **January 2011** up to **June 2012** are not `null`.

```
Create Member CurrentCube.[Measures].[Sales] As null;

Scope( ( { [Date].[Calendar].[Month].&[2011]&[1] :
           [Date].[Calendar].[Month].&[2012]&[6] },
        [Measures].[Sales] ) );
This = [Measures].[Sales Amount];
End Scope;
```

We are going to use this measure to forecast its values for the next year. We've deliberately used a calculated measure that is equal to the original measure, `Sales Amount`, because the latter one already has values in that period. In other words, we'll be able to test how good our forecasting expression is by comparing it to the actual sales data.

Once you're done, deploy the changes – preferably using the **BIDS Helper**, if not SSDT itself.

Then, start SQL Server Management Studio and connect to your SSAS 2016 instance. Click on the **New Query** button and check that the target database is Adventure Works DW 2016.

Write this query:

```
SELECT
    { [Measures].[Sales] } ON 0,
    { Descendants( [Date].[Calendar].[Calendar Year].&[2012],
                    [Date].[Calendar].[Month] ) } ON 1
FROM
    [Adventure Works]
```

Once executed, the query returns 12 months of the year 2012. Half of them have values; the other half are blank:

	Sales
January 2012	\$4,096,554.84
February 2012	\$3,392,353.39
March 2012	\$2,175,637.22
April 2012	\$3,454,151.94
May 2012	\$2,544,091.11
June 2012	\$1,872,701.98
July 2012	(null)
August 2012	(null)
September 2012	(null)
October 2012	(null)
November 2012	(null)
December 2012	(null)

Now, let's see if we can predict the values for those six empty months based on the previous years and the shape of the curve in the previous year on a monthly granularity.

How to do it...

We're going to define six calculated measures and add them to the columns axis:

1. Add the `WITH` part of the query.
2. Create the calculated measure `Sales PP` and define it as the value of the measure `Sales` in the parallel period.
3. Create the calculated measure `Sales YTD` and define it as a year-to-date value of the `Sales` measure.
4. Create the calculated measure `Sales PP YTD` and define it as a year-to-date value of the `Sales` measure in the parallel period. The YTD value should only be calculated up to the parallel period of the last month with the data. For this, you might need some help, so here's the syntax:

```
Sum(
    PeriodsToDate( [Date].[Fiscal].[Fiscal Year],
        ParallelPeriod( [Date].[Fiscal].[Fiscal Year], 1,
            Tail( NonEmpty( { null :
                [Date].[Fiscal].CurrentMember
            },
            [Measures].[Sales] ),
            1 ).Item(0) ) ),
    [Measures].[Sales] )
```

5. Define a calculated measure `Ratio` that is equal to the ratio of the YTD value versus the PP YTD value. Don't forget to take care of possible division by zero (using the `iif()` function).
6. Define a calculated measure `Forecast` that is equal to the parallel period's value of the measure `Sales` corrected (multiplied) by the measure `Ratio`.
7. Define a calculated measure `Forecast YTD` that is equal to the sum of year-to-date values of the measures `Sales` and `Forecast`, but only for months when `Sales` is `null`.
8. Add all those measures on the columns of the query and verify that your query looks like the following one:

```
WITH
MEMBER [Measures].[Sales PP] AS
    ( ParallelPeriod( [Date].[Fiscal].[Fiscal Year], 1,
        [Date].[Calendar].CurrentMember ),
    [Measures].[Sales] )
    , FORMAT_STRING = '$#,##0.00'
MEMBER [Measures].[Sales YTD] AS
    Sum(
```

```

How it works...

The first calculated measure, Sales PP, represents a value of the measure, Sales, in the parallel period—the previous year in this case. This value will serve as a basis for calculating the value of the same period in the current year later. Notice that the measure, Sales PP, has values in each month.

The second calculated measure, Sales YTD, is used as one of the values in the Ratio measure, the measure which determines the growth rate and which is subsequently used to correct the parallel period value by the growth ratio. Notice that the Sales YTD values remain constant after **June 2012** because the values of the measure it depends on, Sales, are empty in the second half of the fiscal year.

The third calculated measure, `Sales PP YTD`, is a bit more complex. It depends on the `Sales PP` measure and should serve as the denominator in the growth rate calculation. However, values of the `Sales PP` measure are not empty in the second half of the year, which means that the cumulative sum would continue to grow. This would corrupt the ratio because the ratio represents the growth rate of the current period versus the previous period, the year-to-date of each period. If one stops, the other should stop too. That's why there's an additional part in the definition that takes care of finding the last period with data and limits the parallel period to the exact same period. This was achieved using the `Tail-NonEmpty-Item` combination, where the `NonEmpty()` function looks for non-empty members up to the current period, `Tail()` takes the last one, and the `Item()` function converts that into a single member. Notice in the previous screenshot that it works exactly as planned. `Sales PP YTD` stops growing when `Sales YTD` stops increasing; all because `Sales` is empty.

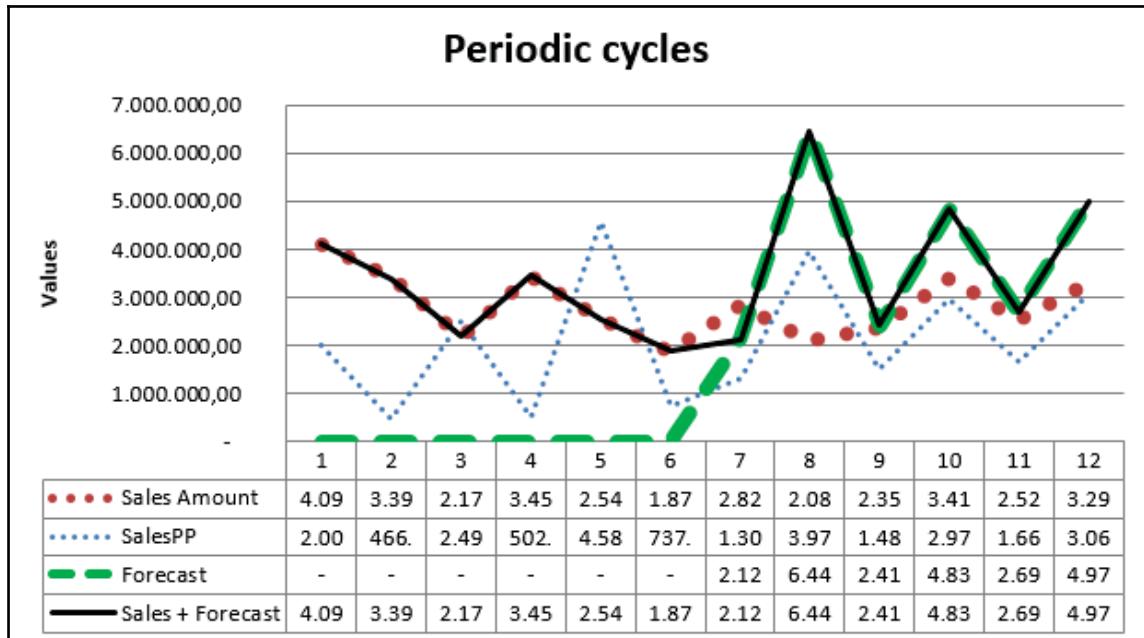

Once we have that fixed, we can continue and build the `Ratio` measure, which as stated earlier, represents the growth rate between all the periods in the current year so far versus the same periods in the previous year. As both of the year-to-date measures become constant at some point in time, the ratio also becomes constant, as visible in the previous screenshot.

The `Forecast` measure is where we take the value of the same period in the previous year and multiply it by the growth rate in the form of the `Ratio` measure. That means we get to preserve the shape of the curve from the previous year while we increase or decrease the value of it by an appropriate factor. It is important to notice that the ratio is not constant, it changes in time, and it adjusts itself based on all the year-to-date values – if they exist. When there aren't any, it becomes a constant.

Finally, the last calculated measure, `Forecast YTD`, is here to show what would have happened to the `Sales YTD` measure if there were values in the last six months of that year. Of course, it does that by summing the year-to-date values of both the `Sales` and `Forecast` measures.

There's more...

The following figure illustrates the principle behind the periodic cycles' calculation quite easily:

The **Sales Amount** series (big dots) represents values of the original measure, the one we used in the scope. The **SalesPP** series (small dots) represents the values of the Sales Amount measure in the previous year's months. The **Forecast** series (broken line) follows the shape of the **Sales PP** series starting from July. Finally, the **Sales + Forecast** series combines sales and forecasts in a way that it switches to forecast data in July to December.

The previous image illustrates that the forecasted values (broken line after June) are not the same as the actual **Sales Amount** data (big dots after June). Some values match perfectly; some don't at all.

There's certainly a possibility of improving the formula for the ratio calculation in a way that incorporates many previous periods and not just the previous year, as in this example, in addition to adding more weight to the recent years, or applying the moving averages to smooth the curve. You are encouraged to experiment with this recipe to get more accurate forecasts of the data.

Other approaches

The technique described in this recipe will fail to achieve good values when applied to non-periodic business processes, or processes with periodic cycles but irregular events inside them. The recipe *Calculating moving averages* in Chapter 3, *Working with Time*, might be a good starting point in those situations.

If you find this recipe interesting, here's another variant in a blog article by *Chris Webb*, one of the early reviewers of this book: <http://tinyurl.com/ChrisSeasonCalcs>.

Finally, data mining and its Time Series algorithm can be a more accurate way of forecasting future values, but that's outside the scope of this book. If you're interested in learning more about it, here are two links to get you started in that direction. One explains what the Time Series algorithm is and the second is *Chris Webb's* application of it: <http://tinyurl.com/DataMiningTimeSeries>

<http://tinyurl.com/ChrisDataMiningForecast>

Allocating non-allocated company expenses to departments

There are two types of expenses; direct and indirect. It is relatively easy for any company to allocate a direct expense to a corresponding department because it actually happens in that department and is in no way associated with other departments. This type of expense is usually allocated in real time when it enters the system. An example of such an expense is salaries.

The other type of expense is an indirect expense, for example, an electricity or heating bill. These expenses are usually entered in the system using a special department like the corporation itself, a common expense department, or simply nothing (a null value). The company, to have a clear picture of how each department is doing, usually wants to allocate these expenses to all departments. Of course, there are many ways of achieving this and none of them are perfect. Because of that, the allocation is usually done at the later stage, not in real time.

For example, the allocation can be implemented in the **ETL (Extract, Transform, Load)** phase. In that case, the modified data enters the **Data Warehouse (DW)** and later the cube. The other approach is to leave the data as it is in the DW and use the MDX script in the cube to modify it. The first scenario will have better performance; the second more flexibility.

Flexibility means that the company can apply several calculations and choose which set of allocation keys fits the best – a sort of what-if analysis. It also means that the company may decide to use multiple allocation schemes at the same time, one for each business process. However, the allocation keys can change in time. Maintaining complex scope statements can become difficult. The performance of such scopes will degrade too. In short, each approach has its advantages and disadvantages.

In this recipe, we'll focus on the second scenario, the one where we apply MDX. After all, this is a book about MDX and its applications. Here, you'll learn how to perform the scope type allocation and how to allocate the values from one member in the hierarchy on its siblings so that the total remains the same. Once you learn the principle, you will be able to choose any set of allocation keys and apply them whenever and wherever required.

Getting ready

In this example, we're going to use the measure **Amount** and two related dimensions, **Account** and **Department**.

Open SQL Server Data Tools (SSDT) and then open the Adventure Works DW 2016 solution. Double-click on the **Adventure Works** cube. Locate the measure **Amount** in the **Financial Reporting** measure group. Go to the next tab, **Dimension Usage**, and check that the two dimensions mentioned previously are related to this measure group.

Now, go to the **Cube Browser** tab and click on the **Analyze in Excel** button on top. If you are being asked about the perspective, choose **Finance**. Then, create a pivot that shows accounts and departments on rows and the value of the measure **Amount** in the data part. Expand the accounts until the member **Operating Expenses** located under **Net Income | Operating Profit** is visible. Expand the departments until all of them are visible. Once you're done, you'll see the following screenshot:

	A	B
1	Row Labels	Amount
2	Balance Sheet	
3	Corporate	\$0.00
4	Executive General and Administration	\$21,634,937.00
5	Inventory Management	\$82,294,417.00
6	Sales and Marketing	(\$103,929,354.00)
7	Net Income	
8	Operating Profit	
9	Operating Expenses	
10	Corporate	\$27,661,868.50
11	Executive General and Administration	\$397,061.00
12	Inventory Management	\$1,316,774.00
13	Manufacturing	\$827,480.00
14	Quality Assurance	\$575,197.00
15	Research and Development	\$11,647,823.00
16	Sales and Marketing	\$660,885.50
17	Gross Margin	
18	Corporate	\$44,390,103.00
19	Research and Development	\$44,390,103.00

Notice a strange thing in the result? The total for the **Corporate** department in the **Operating Expenses** account (the highlighted 27+ millions) is not equal to the sum of the individual departmental values. Roughly 12 million is missing. Why is that?

Double-click on the **Department** dimension in the **Solution Browser** pane. Select the attribute that represents the parent key and check its property, `MembersWithData`, found under the **Parent-Child** group of properties. Notice that it's bold, which means the property has a non-default value. The option that was selected is `NonLeafDataHidden`. That means this parent-child hierarchy hides members that represent the data members of the non-leaf members. In this case there's only one, the **Corporate** member, found on the first level in that hierarchy.

Change the value of this property to `NonLeafDataVisible` and deploy the solution, preferably using the **Deploy Changes Only** deployment mode (configurable in the **Project Properties** form) to speed up the process.

Now, either refresh Excel or return to the **Cube Browser** and reconnect to the cube and click on the **Analyze in Excel** button on top to create a pivot again in Excel (choose the **Finance** perspective again).

A new member will appear on the second level, **Corporate**. This member is not the same as the member on the first level. It is a special member representing its parent's individual value that, together with the value of other siblings, goes into the final value of their parent, the **Corporate** member on the first level. This hidden **Corporate** member, sometimes called the **DATAMEMBER**, has a value of 12+ million, which is now clearly visible in the pivot. The exact amount, marked in the following screenshot, was missing in our equation a moment ago:

	A	B
1	Row Labels	Amount
2	Balance Sheet	
3	Corporate	\$0.00
4	Executive General and Administration	\$21,634,937.00
5	Inventory Management	\$82,294,417.00
6	Sales and Marketing	(\$103,929,354.00)
7	Net Income	
8	Operating Profit	
9	Operating Expenses	
10	Corporate	\$27,661,868.50
11	Corporate	\$12,236,648.00
12	Executive General and Administration	\$397,061.00
13	Inventory Management	\$1,316,774.00
14	Manufacturing	\$827,480.00
15	Quality Assurance	\$575,197.00
16	Research and Development	\$11,647,823.00
17	Sales and Marketing	\$660,885.50
18	Gross Margin	
19	Corporate	\$44,390,103.00
20	Research and Development	\$44,390,103.00

This new member will represent the unallocated expenses that we will try to spread to other departments.

OK, let's start!

Double-click on the **Adventure Works** cube and go to the **Calculations** tab. Choose **Script View**. Position the cursor at the end of the script and follow the steps in the next section.

How to do it...

The solution consists of one calculated measure, two scopes one inside the other, and modifications of the previously defined calculated measure inside each scope:

1. Create a new calculated measure in the MDX script named `Amount alloc` and set it equal to the measure, `Amount`. Be sure to specify `$#,##0.00` as the format of that measure and place it in the same measure group as the original measure:

```
Create Member CurrentCube.[Measures].[Amount alloc]
As [Measures].[Amount]
, Format_String = '$#,##0.00'
, Associated_Measure_Group = 'Financial Reporting'
```

2. Create a scope statement in which you'll specify this new measure, the level two department members, the `Operating Expenses` account, and all of its descendants:

```
Scope( ( [Measures].[Amount alloc],
         [Department].[Departments]
           .[Department Level 02].MEMBERS,
         Descendants( [Account].[Accounts].&[58] ) ) );
```

3. The value in this subcube should be increased by a percentage of the value of the Corporate DATAMEMBER. The percentage of the allocation key that is being used here is going to be the percentage of the individual department in respect to its parents' values. Specify this using the following expression:

```
This = [Measures].[Amount] +
      ( [Department].[Departments].&[1].DATAMEMBER,
        [Measures].[Amount] ) *
      ( [Department].[Departments].CurrentMember,
        [Measures].[Amount] ) /
      Aggregate(
        Except( [Department].[Departments]
          .[Department Level 02]
```

```
.MEMBERS,  
[Department].[Departments]  
. & [1].DATAMEMBER ),  
[Measures].[Amount] );
```

4. Create another scope statement, in which you'll specify that the value of the **Corporate** DATAMEMBER should be null once all allocation is done:

```
Scope( [Department].[Departments].&[1].DATAMEMBER );  
This = null;
```

5. Provide two End Scope statements to close the scopes.

6. The complete code should look like this:

```
Create Member CurrentCube.[Measures].[Amount alloc]  
As [Measures].[Amount]  
, Format_String = '$#,##0.00'  
, Associated_Measure_Group = 'Financial Reporting';  
  
Scope( ([Measures].[Amount alloc],  
[Department].[Departments]  
. [Department Level 02].MEMBERS,  
Descendants( [Account].[Accounts].&[58] ) ) );  
This = [Measures].[Amount] +  
( [Department].[Departments].&[1].DATAMEMBER,  
[Measures].[Amount] ) *  
( [Department].[Departments].CurrentMember,  
[Measures].[Amount] ) /  
Aggregate(  
Except( [Department].[Departments]  
. [Department Level 02]  
.MEMBERS,  
[Department].[Departments]  
. & [1].DATAMEMBER ),  
[Measures].[Amount] );  
Scope( [Department].[Departments].&[1].DATAMEMBER );  
This = null;  
End Scope;  
End Scope;
```

7. Go to the **Perspectives** tab, find the **Finance** measure group (in columns) and the **Amount alloc** measure (in rows, bottom one) and fill the checkbox so that this new measure appears in the **Finance** perspective in Excel.

8. Deploy the changes using the BIDS Helper for 2016 or SSDT itself.
9. Go to the **Cube Browser**, reconnect and add the new measure in the pivot or simply refresh the existing Excel and add the new measure; either should be fine.
10. Verify that the result matches the following screenshot. The highlighted cells are the cells for which the value is changed. The **Corporate** member has no value, while the individual members are increased in proportion to their initial value. Beneath, the total remains the same:

	A	B	C
1	Row Labels	Amount	Amount alloc
2	+ Balance Sheet		
3	+ Corporate	\$0.00	\$0.00
4	Executive General and Administration	\$21,634,937.00	\$21,634,937.00
5	Inventory Management	\$82,294,417.00	\$82,294,417.00
6	Sales and Marketing	(\$103,929,354.00)	-\$103,929,354.00
7	+ Net Income		
8	+ Operating Profit		
9	+ Operating Expenses		
10	+ Corporate	\$27,661,868.50	\$27,661,868.50
11	Corporate	\$12,236,648.00	
12	Executive General and Administration	\$397,061.00	\$712,044.87
13	Inventory Management	\$1,316,774.00	\$2,361,355.50
14	Manufacturing	\$827,480.00	\$1,483,910.26
15	Quality Assurance	\$575,197.00	\$1,031,494.09
16	Research and Development	\$11,647,823.00	\$20,887,905.50
17	Sales and Marketing	\$660,885.50	\$1,185,158.28
18	+ Gross Margin		
19	+ Corporate	\$44,390,103.00	\$44,390,103.00
20	Research and Development	\$44,390,103.00	\$44,390,103.00

How it works...

The new calculated measure is used for allocating the values; the original measure preserves its values. This is not the only way of performing the allocation, but it's the one that suits us now because it allows us to easily compare the original and the new values. If you're interested in the other approach, skip to the next section, which illustrates how to allocate values directly in the original measure.

The new calculated measure is defined to be an alias for the **Amount** measure, meaning it will return the exact same value.

The scope statement is used for specifying the subcube for which we want to apply a different evaluation of the cells. This subcube is formed using the new measure, the **Operating Expenses** account and all of its descendants, and finally all the departments in level two of the `Department`.`Departments` hierarchy. Once we have established this scope, we can apply the new calculation.

The new calculation basically says this: take the original **Amount** measure's value for the current context of that subcube and increase it by a percentage of the **Amount** measure's value of the corporate DATAMEMBER. The sum of all the percentages should naturally be 1 for the total to remain the same.

The percentage is a ratio of the current member's value versus the aggregated value of all its siblings, except the corporate DATAMEMBER. We're skipping that member because that's the member whose value we're dividing among its siblings. We don't want some of it to return to that member again. Actually, we're not deducing its value by this expression; we're merely evaluating a proper percentage of it, which we will use later on to increase the value of each sibling. That's why there was a need for the last statement in that scope. That statement resets the value of the corporate DATAMEMBER.

There's more...

The other way around this is to use an existing measure while keeping the original value in the separate calculated measure. Here's how the MDX script would look in that case:

```
Create Member CurrentCube.[Measures].[Amount preserve]
As [Measures].[Amount]
, Format_String = '$#,##0.00'
, Associated_Measure_Group = 'Financial Reporting' ;

Freeze( ( [Measures].[Amount preserve] ) );

Scope( ( [Measures].[Amount],
```

```
[Department].[Departments]
    .[Department Level 02].MEMBERS,
Descendants( [Account].[Accounts].&[58] ) ) );
This = [Measures].[Amount preserve] +
    ( [Department].[Departments].&[1].DATAMEMBER,
[Measures].[Amount preserve] ) *
    ( [Department].[Departments].CurrentMember,
[Measures].[Amount preserve] ) /
Aggregate(
    Except( [Department].[Departments]
        .[Department Level 02].MEMBERS,
[Department].[Departments]
        .&[1].DATAMEMBER ),
[Measures].[Amount preserve] );
Scope( [Department].[Departments].&[1].DATAMEMBER );
This = null;
End Scope;
End Scope;
```

At first, it looks like the regular and calculated measures have just switched their positions inside the code. However, there's more to it; it's not that simple.

A calculated measure referring to another measure is in fact a **pointer** to that measure's value, not a constant. To evaluate its expression, the referred measure has to be evaluated first.

The assignment inside the `Scope()` statement (the first `This` part) uses the calculated measure, which requires the value of the original `Amount` measure to be evaluated. However, the `Amount` measure is used in the very same scope definition, so to evaluate the `Amount` measure, the engine has to enter the scope and evaluate the calculated measure specified in the assignment in that scope. Now we're in the same position we started from, which means we've run into an infinite recursion. Seen from that perspective, it becomes obvious we should change something in the script.

Just before the `Scope()` statement, we have added a `Freeze()` statement. The MDX `Freeze()` statement locks the cell value of the **Amount** so that changes to other cells in the subsequent `Scope()` statement have no effect on the **Amount**. The `Freeze()` statement takes a snapshot of the subcube, which is provided as its argument, and the snapshot was taken at a particular position in the MDX script. Using `Freeze()`, we have prevented the reevaluation of the calculated measure in all subsequent expressions. Therefore, the `Scope()` statement will not end up in infinite recursion. The assignment inside the scope takes the snapshot value of the calculated measure; it doesn't trigger its reevaluation. In other words, there's no infinite recursion with the use of the `Freeze()` statement.

Here's the screenshot of the **Analyze in Excel** in this case:

	A	B	C
1	Row Labels	Amount	Amount preserve
2	+ Balance Sheet		
3	□ Corporate	\$0.00	\$0.00
4	Executive General and Administration	\$21,634,937.00	\$21,634,937.00
5	Inventory Management	\$82,294,417.00	\$82,294,417.00
6	Sales and Marketing	(\$103,929,354.00)	-\$103,929,354.00
7	+ Net Income		
8	□ Operating Profit		
9	+ Operating Expenses		
10	□ Corporate	\$27,661,868.50	\$27,661,868.50
11	Corporate		\$12,236,648.00
12	Executive General and Administration	\$712,044.87	\$397,061.00
13	Inventory Management	\$2,361,355.50	\$1,316,774.00

17	Sales and Marketing	\$1,185,158.28	\$660,885.50
18	+ Gross Margin		
19	□ Corporate	\$44,390,103.00	\$44,390,103.00
20	Research and Development	\$44,390,103.00	\$44,390,103.00

By looking at the highlighted rows, it looks like the measures have switched places, but now we know the required expressions in the MDX script are not done that way. We had to use the `Freeze()` statement because of the difference between regular and calculated measures and how they get evaluated.

If you want to learn more about the `Freeze()` statement, here's a link to the MSDN site: <http://tinyurl.com/MDXFreeze>

Although this approach allows for drill through (because we're not using a calculated measure), the values returned will not match the cube's data. This is because allocations have been implemented in the MDX script, not in the original DW data.

Choosing a proper allocation scheme

This recipe showed how to allocate the values based on the key, which is calculated as a percentage of the value of each member against the aggregate of all the other siblings to be increased. Two things are important here: we've used the same measure, **Amount**, and we've used the same coordinate, **Departments**, in the cube. However, this doesn't have to be the case.

We can choose any measure we want, any that we find appropriate. For example, we might have allocated the values based on the **Sales Amount**, **Total Product Cost**, **Order Count**, or anything similar. We might have also taken another coordinate for the allocation. For example, there is a **Headcount** member in the **Account.Accounts** hierarchy. We could have allocated **Operating Expense** per the number of headcounts.

To conclude, it is totally up to you to choose your allocation scheme as long as the sum of the allocation percentages (ratios) remains 1.

Analyzing the fluctuation of customers

Every company takes care of its customers, or at least it should, because it is relatively easy to lose one while it's much harder to acquire a new one.

There are many ways to perform analysis on customers. In this recipe, we are going to highlight a few techniques that allow us to get some easy-to-understand indicators:

- The number of loyal customers
- The number of new customers
- The number of lost customers
- Which customers are in a particular group

The idea is pretty simple to understand, so let's start.

Getting ready

Start SQL Server Management Studio and connect to your SSAS 2016 instance. Click on the **New Query** button and check that the target database is Adventure Works DW 2016.

In this example, we're going to use the Customer and Date dimensions and the Customer Count measure, which can be found in the Internet Customers measure group. Here's the query we'll start from:

```
SELECT
    { [Measures].[Customer Count] } ON 0,
    { [Date].[Calendar].[Calendar Quarter].MEMBERS } ON 1
FROM
    [Adventure Works]
```

Once executed, the query returns 40 quarters on the rows.

Our task in this recipe is to make the necessary calculation to have indicators of customer flow. In other words, our task is to get the count of new, loyal, and lost customers as an expression that works in any period or context in general.

How to do it...

The solution consists of five calculated measures that we need to define in the query and then use on the columns:

1. Add the WITH part of the query.
2. Create the first calculated measure, name it Agg TD and define it as an inception-to-date calculation of the measure Customer Count.
3. Create the second calculated measure, name it Agg TD prev and define it similarly to the previous measure, only this time limit the time range to the member that is previous to the current member.
4. Create the Lost Customers calculated measure and define it as the difference between the Agg TD measure and the Customer Count measure.
5. Create the New Customers calculated measure and define it as the difference between the Agg TD measure and the Agg TD prev measure.
6. Create the Loyal Customers calculated measure and define it as the difference between the Customer Count measure and the New Customers measure.
7. Include all the calculated measures on the columns axis of the query.
8. Verify that the query looks like the following:

```
WITH
MEMBER [Measures].[Agg TD] AS
    Aggregate( null : [Date].[Calendar].CurrentMember,
               [Measures].[Customer Count] )
MEMBER [Measures].[Agg TD prev] AS
```

```

        Aggregate( null : [Date].[Calendar].PrevMember,
                    [Measures].[Customer Count] )
MEMBER [Measures].[Lost Customers] AS
    [Measures].[Agg TD] - [Measures].[Customer Count]
MEMBER [Measures].[New Customers] AS
    [Measures].[Agg TD] - [Measures].[Agg TD prev]
MEMBER [Measures].[Loyal Customers] AS
    [Measures].[Customer Count] - [Measures].[New Customers]
SELECT
    { [Measures].[Customer Count],
      [Measures].[Agg TD],
      [Measures].[Agg TD prev],
      [Measures].[Lost Customers],
      [Measures].[New Customers],
      [Measures].[Loyal Customers] } ON 0,
    { [Date].[Calendar Quarter].MEMBERS } ON 1
FROM
    [Adventure Works]

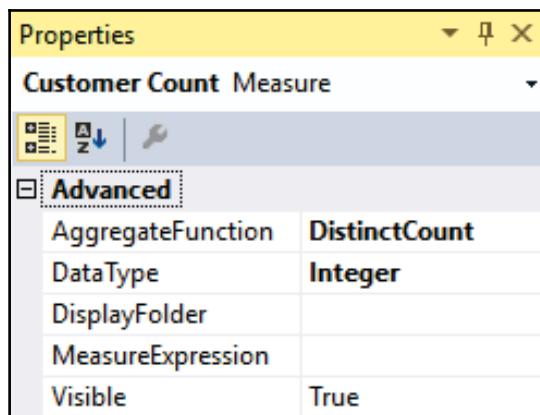

```

9. Run the query and observe the results, especially the last three calculated measures. It is obvious that in the initial phase of this company there was a problem with retaining existing customers.

	Customer Count	Agg TD	Agg TD prev	Lost Customers	New Customers	Loyal Customers
Q1 CY 2010	(null)	(null)	(null)	(null)	(null)	(null)
Q2 CY 2010	(null)	(null)	(null)	(null)	(null)	(null)
Q3 CY 2010	(null)	(null)	(null)	(null)	(null)	(null)
Q4 CY 2010	14	14	(null)	(null)	14	(null)
Q1 CY 2011	438	452	14	14	438	(null)
Q2 CY 2011	561	1,013	452	452	561	(null)
Q3 CY 2011	566	1,579	1,013	1,013	566	(null)
Q4 CY 2011	651	2,230	1,579	1,579	651	(null)
Q1 CY 2012	724	2,954	2,230	2,230	724	(null)
Q2 CY 2012	744	3,698	2,954	2,954	744	(null)
Q3 CY 2012	809	4,507	3,698	3,698	809	(null)
Q4 CY 2012	988	5,455	4,507	4,467	948	40
Q1 CY 2013	3,523	8,031	5,455	4,508	2,576	947
Q2 CY 2013	5,021	11,414	8,031	6,393	3,383	1,638
Q3 CY 2013	5,312	14,569	11,414	9,257	3,155	2,157
Q4 CY 2013	6,015	17,978	14,569	11,963	3,409	2,606
Q1 CY 2014	834	18,484	17,978	17,650	506	328
Q2 CY 2014	(null)	18,484	18,484	18,484	(null)	(null)
Q3 CY 2014	(null)	18,484	18,484	18,484	(null)	(null)
Q4 CY 2014	(null)	18,484	18,484	18,484	(null)	(null)

How it works...

The expressions used in this example are relatively simple expressions, but that doesn't necessarily mean that they are easy to comprehend. The key to understanding how these calculations work is in realizing that a distinct count type of measure was used. What's special about that type of aggregation is that it is not an additive aggregation. The measure, Customer Count, is a distinct type of measure. You can verify that by checking the **AggregateFunction** property of the measure, which is **DistinctCount**, as shown in the following screenshot:

In this recipe, we've taken advantage of non-additive behavior of the distinct count aggregation and managed to get really easy-to-memorize formulas.

We're starting with the two special calculated measures. The first one [Agg_TD] calculates the inception-to-date value of the Customer Count measure. An ordinary measure with Sum aggregation would sum all the values up to the current point in time. However, a non-additive Distinct Count type of measure behaves differently. It returns the count of distinct customers up to the current point in time, not their sum. That value can be greater or equal to the number of customers who have Internet orders in any period and less than or equal to the total number of customers.

The second calculated measure [Agg_TD_prev] does the same thing, except that it stops in the previous period.

Combining those two measures with the original Customer Count measure leads to the solution for the other three calculated measures.

The Lost Customers measure gets the value obtained by subtracting the count of customers in the current period from the count of customers so far. The New Customers measure gets the value that is equal to the difference between those first two calculated measures. Again, this evaluates to the number of customers so far minus the number of customers up to the previous period. What's left are those that were acquired in the current time period.

Finally, the Loyal Customers calculated measure is defined as the count of customers in the current period minus the new customers; everything that's in the current period is either a new or a loyal customer.

The two special calculated measures are not required to be in the query or to be visible at all. They are used here only to show how the evaluation takes place.

There's more...

It makes sense to put those definitions in the MDX script so that they can be used in the subsequent calculations by all users. Here's what should go in the MDX script:

```
Create Member CurrentCube.[Measures].[Agg TD] AS
    Aggregate( null : [Date].[Calendar].CurrentMember,
               [Measures].[Customer Count] )
    , Format_String = '#,#'
    , Visible = 0
    , Associated_Measure_Group = 'Internet Customers';

Create Member CurrentCube.[Measures].[Agg TD prev] AS
    Aggregate( null : [Date].[Calendar].PrevMember,
               [Measures].[Customer Count] )
    , Format_String = '#,#'
    , Visible = 0
    , Associated_Measure_Group = 'Internet Customers';

Create Member CurrentCube.[Measures].[Lost Customers] AS
    [Measures].[Agg TD] - [Measures].[Customer Count]
    , Format_String = '#,#'
    , Associated_Measure_Group = 'Internet Customers';

Create Member CurrentCube.[Measures].[New Customers] AS
    [Measures].[Agg TD] - [Measures].[Agg TD prev]
    , Format_String = '#,#'
```

```
, Associated_Measure_Group = 'Internet Customers';

Create Member CurrentCube.[Measures].[Loyal Customers] AS
[Measures].[Customer Count] - [Measures].[New Customers]
, Format_String = '#,#'
, Associated_Measure_Group = 'Internet Customers';
```

This allows us to identify the customers in those statuses (lost, loyal, and new).

Identifying loyal customers in a period

The period we'll use in this example will be **Q4 CY 2012**. We want to find out who were our first loyal customers. Perhaps we want to reward them or analyze their behavior further to determine what made them stay with us. We'll choose to further analyze their behavior. We have prepared the following query to gather all sorts of measures about those customers:

```
WITH
SET [Loyal Customers] AS
    NonEmpty( [Customer].[Customer].[Customer].MEMBERS,
              [Measures].[Customer Count] ) -
(
    NonEmpty( [Customer].[Customer].[Customer].MEMBERS,
              [Measures].[Agg TD] ) -
    NonEmpty( [Customer].[Customer].[Customer].MEMBERS,
              [Measures].[Agg TD prev] )
)
SELECT
{ [Measures].[Internet Order Count],
  [Measures].[Internet Order Quantity],
  [Measures].[Internet Sales Amount],
  [Measures].[Internet Gross Profit],
  [Measures].[Internet Gross Profit Margin],
  [Measures].[Internet Average Sales Amount],
  [Measures].[Internet Average Unit Price] } ON 0,
{ [Loyal Customers] } ON 1
FROM
[Adventure Works]
WHERE
( [Date].[Calendar].[Calendar Quarter].&[2012]&[4] )
```

The previous query has **Q4 CY 2012** in the slicer and several measures on the columns. The set on the rows **[Loyal Customers]** is defined as the difference among the three sets.

The expression for the Loyal Customers set is in the form of $Y = A - (B - C)$, which is similar to how we calculate the Loyal Customers measure in our initial solution.

Here, we are repeating the logic we used in the initial solution for calculating the Loyal Customers measure:

```
[Loyal Customers] = [Customer Count] - [New Customers]  
[New Customers] = [Customers Inception-to-date (Agg TD)] -  
[Customers previous to the current member (Agg TD prev)]
```

The logic is similar: the difference is that we are now doing the set operation. To get the set A, B, and C, we used the NonEmpty() function and the following three calculated measures as the second argument of the NonEmpty() function:

```
[Measures].[Customer Count]  
[Measures].[Agg TD]  
[Measures].[Agg TD prev]
```

Yes, using these three sets we got 40 loyal customers. Here's the screenshot with their values:

	Internet Order Count	Internet Order Quantity	Internet Sales Amount	Internet Gross Profit	Inte
Adrienne Gutierrez	1	5	\$638.95	\$238.49	
Alisha G. Zhu	1	2	\$2,452.34	\$894.03	
Alvin E. Hu	1	4	\$2,362.27	\$1,080.84	
Anne B. Hernandez	1	4	\$2,369.96	\$1,085.65	
April Deng	1	5	\$2,365.94	\$1,079.58	
Arthur K. Jiménez	1	3	\$1,763.97	\$632.97	
Blake Anderson	1	2	\$2,374.98	\$1,088.79	
Brandi D. Gill	1	3	\$2,428.05	\$926.10	
Candace Fernandez	1	1	\$2,294.99	\$1,043.01	
Clayton Kumar	1	2	\$751.34	\$286.53	
Darren Townsend	1	1	\$1,700.99	\$618.48	
Dawn E. Huang	1	1	\$539.99	\$245.41	
Denise L. Martinez	1	4	\$2,344.96	\$1,074.29	
Derek M. Xu	1	3	\$1,729.97	\$636.62	
Dwayne H. Navarro	1	2	\$777.34	\$302.81	
Frank F. Navarro	1	4	\$2,369.96	\$1,085.65	
Franklin Raji	1	4	\$2,318.96	\$1,054.45	
Hailey P. Russell	1	5	\$2,542.31	\$930.55	
Jacqueline Powell	1	2	\$2,297.28	\$1,044.44	

It's worth mentioning that you can build several dynamic sets in the MDX script, which would represent the customers in the particular status. Here's the expression for the dynamic Loyal Customers set:

```
Create Dynamic Set CurrentCube.[Loyal Customers] AS  
    NonEmpty( [Customer].[Customer].[Customer].MEMBERS,  
              [Measures].[Customer Count] ) -  
    (  
        NonEmpty( [Customer].[Customer].[Customer].MEMBERS,  
                  [Measures].[Agg TD] ) -  
        NonEmpty( [Customer].[Customer].[Customer].MEMBERS,  
                  [Measures].[Agg TD prev] )  
    );
```

If you're wondering whether this only applies to customer analysis, the answer is no! It doesn't have to be a customer dimension; it can be any dimension. The principles apply in the same way.

More complex scenario

There are other options we can use for customer analysis. For example, we might want to combine two or more periods.

We know there were 40 loyal customers in the last quarter of the year 2012. A perfectly logical question arises—what happened to them afterwards? Are they still loyal in Q2 in the following year? If yes, how many of them?

Let's find out:

```
SELECT  
    { [Measures].[Internet Order Count],  
      [Measures].[Internet Order Quantity],  
      [Measures].[Internet Sales Amount],  
      [Measures].[Internet Gross Profit],  
      [Measures].[Internet Gross Profit Margin],  
      [Measures].[Internet Average Sales Amount],  
      [Measures].[Internet Average Unit Price] } ON 0,  
    { Exists( [Loyal Customers Set],  
             ( [Measures].[Customer Count],  
               [Date].[Calendar].[Calendar Quarter].&[2013]&[2] ),  
             'Internet Customers' ) } ON 1  
FROM  
    [Adventure Works]  
WHERE
```

```
( [Date].[Calendar].[Calendar Quarter].&[2012]&[4] )
```

The query is similar to the previous one, except here we have an extra construct using the `Exists()` function, the variant with the measure group name. What this function does is take the Loyal Customers Set in Q4 2012 and reduces it to a set of members who also have values in the following year's Q2.

The result shows 14 customers out of 40 are identified as loyal customers also in Q2 2013:

	Internet Order Count	Internet Order Quantity	Internet Sales Amount	Internet Gross Profit	Internet C
Alvin E. Hu	1	4	\$2,362.27	\$1,080.84	
Anne B. Hernandez	1	4	\$2,369.96	\$1,085.65	
April Deng	1	5	\$2,365.94	\$1,079.58	
Blake Anderson	1	2	\$2,374.98	\$1,088.79	
Candace Fernandez	1	1	\$2,294.99	\$1,043.01	
Denise L. Martinez	1	4	\$2,344.96	\$1,074.29	
Dwayne H. Navarro	1	2	\$777.34	\$302.81	
Janet G. Alvarez	1	3	\$2,334.97	\$1,063.75	
Jessie Liu	1	1	\$2,294.99	\$1,043.01	
Kaitlyn J. Henderson	1	4	\$2,514.93	\$933.21	
Kari C. Alvarez	1	2	\$2,329.99	\$1,064.92	
Kyle Patterson	1	4	\$2,318.96	\$1,054.45	
Lisa Cai	1	2	\$2,329.98	\$1,064.91	
Todd M. Gao	1	4	\$2,369.96	\$1,085.65	

The alternative approach

Chris Webb has an alternative solution for customer analysis on his blog, at: <http://tinyurl.com/ChrisCountingCustomers>.

Implementing the ABC analysis

ABC analysis is a method of identifying and classifying items, based on their impact, into three regions: A, B, and C. It's an extension of the 80-20 rule, also known as the **Pareto** principle, which states that for many events, roughly 80 percent of the effects come from 20 percent of the causes. In one definition of ABC analysis, the top 20 percent of the causes, the important part, are further divided into two subgroups: A (the top 5 percent) and B (the subsequent 15 percent), and the 80 percent of effects they contribute to into segments of 30 percent and 50 percent. These are the ratios we're going to use in this recipe. There are, of course, other definitions like 10/20/70. It really depends on the user needs and you're free to change it and experiment.

ABC analysis is a very valuable tool that can be found mostly in highly-specialized applications, for example, in an inventory management application. This recipe will demonstrate how to perform ABC analysis on the cube.

Getting ready

Start SQL Server Management Studio and connect to your SSAS 2016 instance. Click on the **New Query** button and check that the target database is Adventure Works DW 2016.

In this example, we're going to use the `Product` dimension. Here's the query we'll start from:

```
SELECT
    { [Measures].[Internet Gross Profit] } ON 0,
    NON EMPTY
    { [Product].[Product].[Product].MEMBERS } ON 1
FROM
    [Adventure Works]
WHERE
    ( [Product].[Status].&[Current],
        [Date].[Calendar Year].&[2012] )
```

Once executed, the query returns all active products and their profit in Internet sales for the year 2012. The result shows 63 active products.

Now, let's see how we can classify them.

How to do it...

The solution consists of two calculated measures and four named sets. The last measure returns the group A, B, or C.

1. Add the WITH part of the query.
2. Define a new calculated measure as an alias for the measure on the columns and name it Measure for ABC.
3. Define a named set, Set for ABC, which returns only products for which the Internet profit is not null using the previously-defined alias measure:

```
NonEmpty( [Product].[Product].[Product].MEMBERS,  
          [Measures].[Measure for ABC] )
```

4. Using the following syntax, define three named sets: A, B, and C:

```
SET [A] AS  
    TopPercent( [Set for ABC], 30,  
                [Measures].[Measure for ABC] )  
SET [B] AS  
    TopPercent( [Set for ABC], 80,  
                [Measures].[Measure for ABC] ) - [A]  
SET [C] AS  
    [Set for ABC] - [A] - [B]
```

5. Finally, define a calculated measure ABC group that returns the letter A, B, or C based on the contribution of each product. Use the following expression:

```
iif( IsEmpty( [Measures].[Measure for ABC] ), null,  
    iif( Intersect( [A],  
                    [Product].[Product].CurrentMember  
                    ).Count > 0,  
        'A',  
        iif( Intersect( [B],  
                        [Product].[Product]  
                        .CurrentMember  
                        ).Count > 0,  
            'B',  
            'C'  
        )  
    )  
)
```

6. Add that last calculated measure on the columns and replace the existing measure with the Measure for ABC calculated measure.
7. Run the query, which should now look like:

```
WITH
MEMBER [Measures].[Measure for ABC] AS
    [Measures].[Internet Gross Profit]
SET [Set for ABC] AS
    NonEmpty( [Product].[Product].[Product].MEMBERS,
        [Measures].[Measure for ABC] )
SET [A] AS
    TopPercent( [Set for ABC], 30,
        [Measures].[Measure for ABC] )
SET [B] AS
    TopPercent( [Set for ABC], 80,
        [Measures].[Measure for ABC] ) -
    [A]
SET [C] AS
    [Set for ABC] - [A] - [B]
MEMBER [Measures].[ABC Group] AS
    iif( IsEmpty( [Measures].[Measure for ABC] ), null,
        iif( Intersect( [A],
            [Product].[Product].CurrentMember
        ).Count > 0,
            'A',
            iif( Intersect( [B],
                [Product].[Product]
                    .CurrentMember
            ).Count > 0,
                'B',
                'C' ) ) )
SELECT
    { [Measures].[Measure for ABC],
        [Measures].[ABC Group] } ON 0,
NON EMPTY
    { [Product].[Product].[Product].MEMBERS } ON 1
FROM
    [Adventure Works]
WHERE
    ( [Product].[Status].&[Current],
        [Date].[Calendar Year].&[2012] )
```

8. Verify that the result matches the following screenshot:

	Measure for ABC	ABC Group
All-Purpose Bike Stand	\$99.53	C
AWC Logo Cap	\$16.54	C
Classic Vest, S	\$39.75	C
Fender Set - Mountain	\$68.80	C
Half-Finger Gloves, L	\$15.33	C
Half-Finger Gloves, M	\$15.33	C
Half-Finger Gloves, S	\$15.33	C
HL Mountain Tire	\$87.64	C
HL Road Tire	\$81.63	C
Hydration Pack - 70 oz.	\$68.85	C
LL Road Tire	\$67.26	C
Long-Sleeve Logo Jersey, L	\$34.49	C
Long-Sleeve Logo Jersey, M	\$11.50	C
ML Mountain Tire	\$18.77	C
ML Road Tire	\$31.29	C
Mountain Bottle Cage	\$68.79	C
Mountain Tire Tube	\$9.37	C
Mountain-200 Black, 38	\$3,129.03	B
Mountain-200 Black, 42	\$4,172.03	A
Mountain-200 Black, 46	\$6,258.05	A
Mountain-200 Silver, 38	\$5,271.85	A

How it works...

The alias for the measure, `Internet Gross Profit`, in the form of the calculated measure, `Measure for ABC`, together with the alias for the set on the rows, `Set for ABC`, enables us to have a flexible and readable query. The query is flexible because we can change the measure in a single spot and have the query running another ABC analysis. For example, the analysis of the revenue or the number of orders. It is readable because we're using short but informative names in it instead of the long MDX specific names for members and levels. In addition, we are keeping the syntax short by not having to repeat some expressions. As for the set on the rows, we're not making the query completely flexible; there are still some parts of the query where the mention of a specific hierarchy was not replaced by something more general.

Anyway, let's analyze the main part of the query: sets A, B, and C and the calculated measure, ABC Group.

The TopPercent () function, in combination with a set and a measure, returns the top members from that set. The threshold, required as the second argument of that function, determines which members are returned.

That's a pretty vague description of what this function does because it is not clear which members get returned or how many top members will be returned. Let's see the more detailed explanation.

The behavior of that function can be explained using the list of members sorted in descending order. We don't know in advance how many of them the function will return; the only thing we know is that it will stop at some point.

The members are included up to the point where the ratio (in the form of a percentage) of the cumulative sum versus the total becomes equal to the value provided as the second argument. In our example, we had two such values, 30 and 80; 80 because the second segment is 50 and the sum of 30 and 50 is 80. The function would use all top members up to the point where their sum reaches 30 percent or 80 percent, respectively, of the total value of the set.

So, set A will contain the top products that form 30 percent of the total.

Set B gets calculated as even more: 80 percent of the total. However, that would include also members of set A. That's why we had to exclude them. Set B contains the next 50 percent of the total.

Set C can eventually be calculated as all the rest, meaning the complete set of members, excluding members in both set A and set B. Set C contains the bottom 20 percent of the total.

The calculated measure, ABC Group, basically takes the current member on the rows and checks in which set of three named sets it is. This is done using a combination of the Intersect () function and the Count () function. If there's an intersection, the count will show 1.

When the iteration on the cells starts, each member gets classified as either A, B, or C, based on its score and in which of the three predefined groups it can be found.

There's more...

There are many ways to calculate A, B, or C. I'd like to believe I've shown you the fastest one.

Here's another example to explain what I meant by that.

Use the same query as before, but replace the measure, ABC group, with these two calculations:

```
MEMBER [Measures].[Rank in set] AS
    iif( IsEmpty( [Measures].[Measure for ABC] ), null,
        Rank( [Product].[Product].CurrentMember,
              [Set for ABC],
              [Measures].[Measure for ABC] ) )
    , FORMAT_STRING = '#,#'

MEMBER [Measures].[ABC Group] AS
    iif( IsEmpty( [Measures].[Measure for ABC] ), null,
        iif( [Measures].[Rank in set] <= [A].Count,
            'A',
            iif( [Measures].[Rank in set] <= { [A] + [B] }.Count,
                'B', 'C' ) ) )
```

Run the query and observe the results. They should match the results from the previous query. What changes is the execution time.

In Adventure Works, that change in time is not so obvious, especially in the context of this query. If you want to experience a more noticeable change, use the reseller dimensions. There you'll see a small difference.

Why is the second approach slower?

The initial example illustrates a classic case of set-based thinking. First, we've defined the set A, then we've used it in the definition of set B, and finally we've defined the third set using the previous two. Therefore, we've used a simple and effective set operation – the difference between the sets.

That's not all there is to it. Something else is important. Sets evaluate before the iteration on the cells starts. This means that by the time the engine starts to evaluate the expression in the ABC Group measure, sets have already been evaluated and therefore are sort of a constant. When the iteration starts, the engine compares each member with a maximum of two of those sets. That comparison is again performed using a fast set operation – the intersection of two sets. In short, we completely avoided any iteration in this approach.

Now consider the second example, the one which uses the `Rank` function.

The idea is to have a rank that tells us how good each member was – what position it took. We can use this rank and compare it with the count of members in set A or count of members in both sets A and B. If the rank is a smaller number, we get a match and the member gets the corresponding class because of the calculation.

True, sets A, B, and C are static again, pre-evaluated, but the rank operation, together with the process of counting the number of items in a set, takes time. Here, we're not applying the set-based thinking; we're iterating, although internally, on a set to get the rank while we don't really need that rank at all.

Remember to always look for a set-based alternative if you catch yourself using iteration. Sometimes it will be possible; sometimes it won't. If you have a large cube, it's certainly worth a try.

Tips and tricks

Always check if you can move everything that was on an axis to a named set. Your calculations will be easier.

Consider defining everything in the MDX script because of the advantages of centrally-based calculations (speed, cache, and availability).

When MDX is Not Enough

In this chapter, we will cover the following recipes:

- Using a new attribute to separate members on a level
- Using a distinct count measure to implement histograms over existing hierarchies
- Using a dummy dimension to implement histograms over nonexisting hierarchies
- Creating a physical measure as a placeholder for MDX assignments
- Using a new dimension to calculate the most frequent price
- Using a utility dimension to implement flexible display units
- Using a utility dimension to implement time-based calculations

Introduction

So far, we've been through the basics of MDX calculations. We learned a few tricks regarding time calculations, practiced making concise reports, navigated hierarchies, and analyzed data by applying typical business calculations. Now, we will discuss special topics.

This is a book that follows the cookbook approach, the main topic being MDX. In this chapter, however, we're going to discover that MDX calculations are not always the best solution. It is only one of the possible layers we can start from. The other two layers are the cube design and the underlying data warehouse (DW) model. Each layer depends on the other. A good data model will enable a good cube design which in turn will enable simple MDX calculations.

Whenever we are given a request to get something from the cube, it is not only a request to make an adequate MDX query or calculation and then to return the data, it is something much deeper—a challenge to our cube design and the underlying dimensional model. If the MDX becomes too complex, that's a potential sign there's something wrong with the cube design and that they can also be improved.

This chapter illustrates several techniques to optimize the query response time with a relatively simple change in the cube structure, to simplify cube maintenance and MDX calculations, to enable new analysis or even to make the so-far impossible ones possible. The types of changes we're talking about here are adding new measures or attributes, and even adding a complete dimension.

Calculations are performed by the formula engine at query time. Using regular measures we can avoid a query-time performance decrease. Regular measures have other advantages over the calculated ones which are discussed in this chapter.

Attributes not only enhance the dimension design allowing users to avoid multi-select and problems related to it, they are a potential place for aggregations and therefore a candidate for optimization of reports.

Utility dimensions play a vital role in providing powerful calculations that are easy to maintain in contrast to potential chaos with calculated measures. A variant of the utility dimensions, the dummy dimension, is a convenient structure which enables iteration, allocation, and other useful activities.

Finally, if you find yourself running a lot over leaves in your calculations, you should know that cubes are not designed to do that. Maybe a different granularity from the fact table should be applied or a new dimension should be considered.

These are the things we'll encounter in this chapter. If you can create the calculations in the DSV/DW layer or prepare data there without compromising the cube's flexibility, do it. That way, whatever you implement will be resolved only once, during processing, instead of during every query execution. The idea is to push things down to the lower layers as much as possible so that queries run faster.

By the way, don't worry about MDX, there's still plenty of it here. The only difference is that, in contrast to the previous chapters, here the focus is on other aspects, not just MDX.

Let's start slowly.

Using a new attribute to separate members on a level

In reporting and analysis, there are situations when a certain member (often named NA, unknown, or similar) corrupts the analysis. It makes it hard for end users to focus on the rest of the data. It distracts them by making them think about what this member represents, why it is here, and why it has data associated to it. Other times, the reason may be that the end users need a total without that member. In both of these situations, they remove that member from the result which generates a new MDX query.

It is true, that a combination of a named set without that member and a calculated member as an aggregate of that set can be created in MDX script to simplify the rest of the calculations and the usage of that hierarchy in general. However, this is not the optimal solution.

Is there a better way? Yes, but it requires a dimension redesign. If that's applicable in your case, read on because this recipe shows how to keep your cube design simple and effective, all at the price of a bit of your time invested in the preparation of data.

Getting ready

Open the SQL Server Data Tools (SSDT) and then open the Adventure Works DW 2016 solution. Once it loads, double-click on the **Product** dimension, the dimension where the problematic member will be in this example.

We're going to use the `Color` attribute of the **Product** dimension. If you browse the dimension in the **Browser** tab, you'll see there are ten colors, one of which is NA. The idea is to somehow exclude this color from the list of colors and keep it separate. To do this, we'll need another attribute to separate colors in two groups: colors with the exact name in one group and the NA color in another.

Attributes are built from one or more columns in the underlying dimension table or view. The preferred place for introducing this change is the data warehouse (DW), a view that represents the dimension table from which this dimension is built. Having all of the logic in one place increases the maintainability of the overall solution. However, in order to keep things simple and focus on what's important, we're going to disregard the best practice here and use the data source view (DSV) instead.

How to do it...

Follow these steps to add a new attribute that will be used to separate members on another attribute.

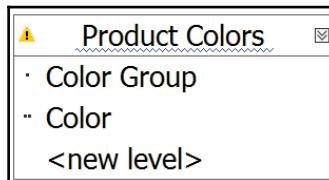

1. Double-click on the **Adventure Works DW** data source view.
2. Locate the **Product** dimension in the **Tables** pane on the left, then right-click and select **New Named Calculation**.
3. Enter `ColorGroupKey` for the **Column** name and this code for the expression:

```
CASE Color WHEN 'NA' THEN 1 ELSE 0 END
```

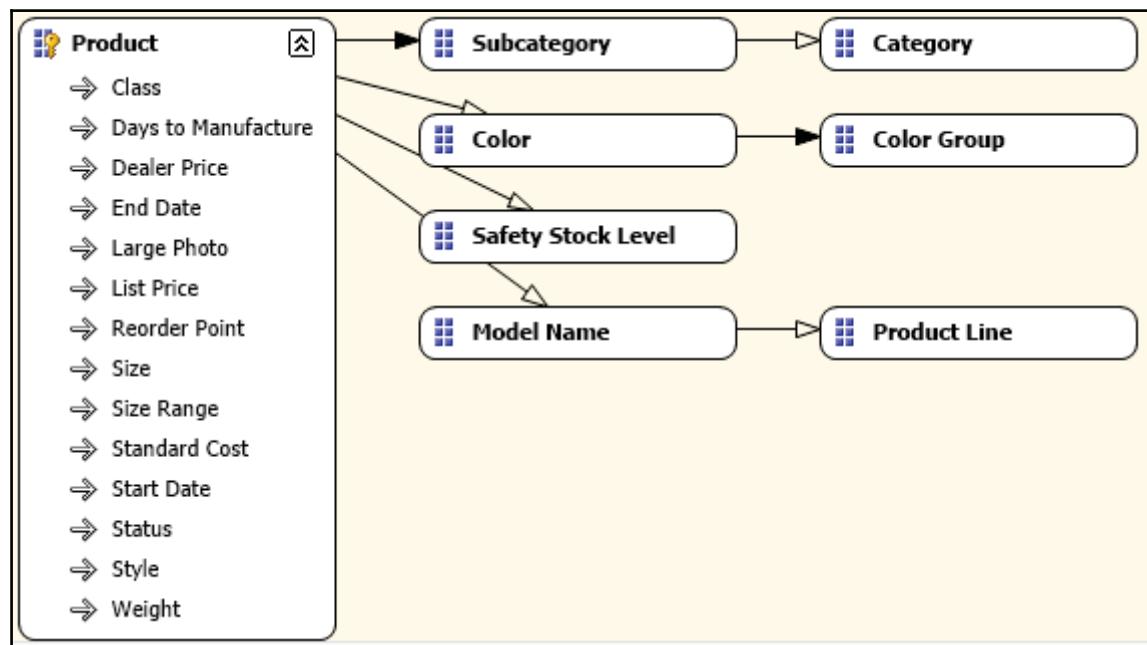

4. Close the dialog and repeat the process for another column. This time, name it `ColorGroupName` and use the following definition:

```
CASE Color WHEN 'NA' THEN 'Unknown colors' ELSE 'Known colors' END
```

5. Close the dialog again and explore the **Product** table to see the result of those two new columns. They should be visible at the end of the table. If everything's OK, close the **Explore Product Table** tab.
6. Now return to the **Product** dimension again; you should see two new calculated columns in the end of the table in the **Data Source View** pane on the right.
7. Drag the `ColorGroupKey` column to the left and drop it in the **Attributes** pane.
8. Rename it to `Color Group`, then navigate to the `NameColumn` property and select the `ColorGroupName` column for that.
9. Set the `OrderBy` property to `Key` in order to preserve the order by key.
10. Drag the newly created `Color Group` attribute to the **Hierarchies** pane followed by the `Color` attribute underneath it. The idea is to create a new user hierarchy.
11. Name the hierarchy `Product Colors` and set the `AllMemberName` in the **Properties** pane to **All Products**. This is a screenshot of the hierarchy `Product Colors`.

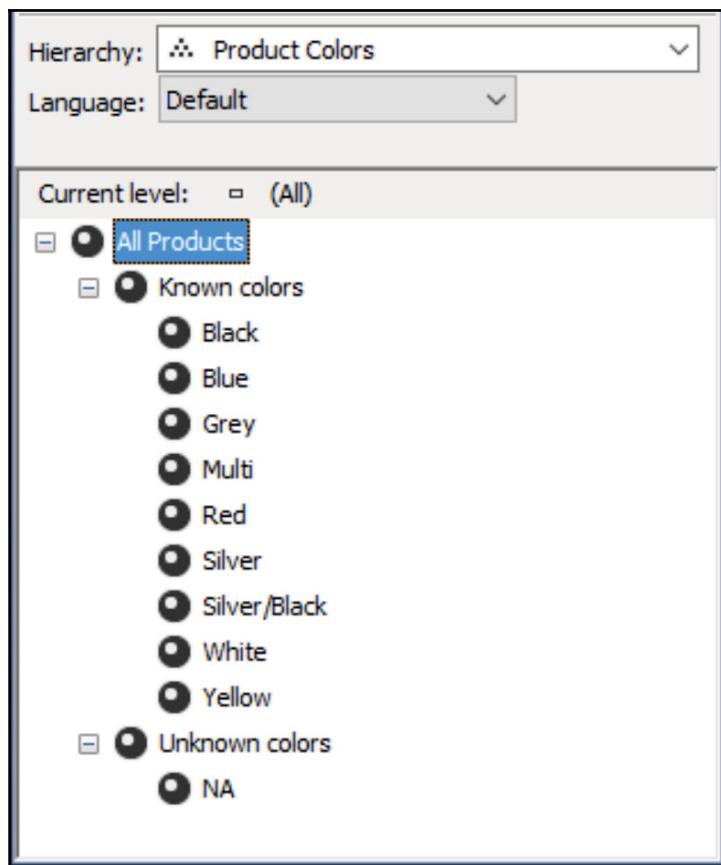

12. Notice the yellow warning sign. Go to the **Attributes Relationships** tab and set the correct relation between the Color and Color Group attributes. In SSDT for SSAS 2012 and 2016, you can click on the **New Attribute Relationship** icon on top. If you are using BIDS for SSAS 2008 R2, you can drag the Color attribute over the Color Group attribute and release it.
13. Select the arrow that points to the Color Group attribute and change the **RelationshipType** property from **Flexible** to **Rigid** in the **Properties** pane. The tip of the arrow should turn black, just like in the following figure:

13. Return to the **Dimension Structure** tab and check that the warning sign is gone.
14. Select the **Product Colors** user hierarchy and set the **DisplayFolder** property to **Stocking**.
15. Select the Color Group attribute and set its visibility to **False** using the **AttributeHierarchyVisible** property.

16. Process the dimension. When it's done, go to the **Browser** tab, reconnect, and verify that the new **Product Colors** user hierarchy works as expected, so that colors are separated in two new nodes, **Known colors** and **Unknown colors**, as shown in the following screenshot:

17. Now process the Adventure Works cube, reconnect and go to the **Browser** tab to click on the **Analyze in Excel** icon on top to open Excel to make a report using the new **Product Colors** user hierarchy which you'll find under the **Stocking** folder of the **Product** dimension. All the four measures shown in the following screenshot are from the Sales Summary measure group.

	A	B	C	D	E
1	Row Labels	Order Quantity	Average Unit Price	Sales Amount	Gross Profit
2	Known colors	226,488	\$640.29	\$108,709,970.29	\$12,084,542.62
3	Black	81,856	\$610.08	\$38,236,124.06	\$4,971,374.95
4	Blue	23,659	\$534.43	\$9,602,850.97	\$605,893.01
5	Multi	25,059	\$27.07	\$649,030.25	\$13,160.89
6	Red	29,187	\$990.68	\$21,597,890.81	\$2,720,764.26
7	Silver	25,023	\$936.10	\$19,777,339.95	\$3,239,562.63
8	Silver/Black	3,931	\$37.35	\$147,483.91	\$38,250.97
9	White	5,217	\$6.85	\$29,745.13	\$12,163.31
10	Yellow	32,556	\$731.52	\$18,669,505.22	\$483,372.60
11	Unknown colors	48,288	\$18.44	\$1,099,303.91	\$466,823.63
12	NA	48,288	\$18.44	\$1,099,303.91	\$466,823.63
13	Grand Total	274,776	\$465.18	\$109,809,274.20	\$12,551,366.25

How it works...

The new attribute `Color` Group plays several roles. It enables natural, by-design subtotals, easy navigation, easy filtering, and keeps further MDX calculations simple and effective.

In order to create it, we've extended the **Product** table with two new columns, `ColorGroupKey` and `ColorGroupName`. We did that in the **Data Source View (DSV)**, although we could have done the same in the dimension table in the **Data Warehouse (DW)**. In fact, it might have been a better decision to go to the DW. However, in order to keep things the way the Adventure Works database is done, we have chosen to use calculated columns in the DSV. In your real project, you should add those calculated columns to the dimension table in the DW.

Why did we use the key-name pair instead of using the name field alone? We have designed the key-name pair for a good reason. By carefully planning the key column value, and setting the `OrderBy` property to `Key`, we have met our needs for ordering. In this example, we've deliberately placed the Known colors value first using the lower key value and ordered the attribute by key instead of by name.

In the process of dimension redesign we did one extra step. We created a natural user hierarchy, `Product Colors`. A natural user hierarchy is beneficial from the perspective of both performance and data navigation.

We also did something else that is important and should not be forgotten-defining relations between the new attribute, `Color Group`, and an existing one, `Color`. Attribute relationships define hierarchical dependencies between attributes. These relationships between attributes can be used by the Analysis Services engine to optimize performance.

Other things we did were more or less cosmetic.

Dimensional processing was required because the structure has changed. The same goes for the cube.

You should also consider redesigning your aggregations. The new attribute has only two members, therefore the aggregation wizard may look for and include it in many combinations with other hierarchies. In other words, with the same amount of space dedicated for aggregations, a low-cardinality attribute can generate more aggregations than the one with more members in it. The more aggregations, the greater the chance of hitting one of them in queries that use this new attribute.

There's more...

Notice that once you redesign your dimension like that, you can do many things relatively easily. One of those things we've already shown is using natural subtotals and ordering of the members in the user hierarchy. The next thing is the filtering of members.

If you need to show only known colors, you can put that single member in the slicer. Having a single member is a much better solution than using multi-select. Not only will the performance be better, but you also avoid problems with tools that have problems with multi-select. Therefore, think about this solution in a much broader sense, not only as a way of isolating unwanted members, but also as a way of avoiding problems with multi-select, and to have simple MDX calculations.

So, when should we consider creating a new attribute?

Well, you know that sometimes a modification like this is just not possible. You can't anticipate all the possible multi-selects that users may want, or you are not allowed to change the dimension structure, or to have the cube down for a certain amount of time. Yes, this can be handled, but your current configuration may be preventing you from doing that smoothly.

Redesigning the aggregations could be beneficial, but it's totally optional. It doesn't have to put you off from implementing a new attribute. The existing aggregations on the `Color` attribute (if any) should be leveraged because of the established attribute relationships.

Nevertheless, the idea of this recipe was to show you how to do it. The final decision of whether you'll do it or not, in the end, entirely yours. Weigh the pros and cons, especially if you have a development environment where you can play, and make a decision based on your findings.

So, where's the MDX?

There isn't any! At least not in this recipe. Remember, the best thing is to keep things simple. This recipe demonstrated how making a small investment in the redesign of your dimension pays off by not having complex MDX calculations. Even better, by not having MDX at all sometimes!

It follows the main idea of the chapter that the solution isn't to make the best possible MDX calculation or query. Quite often, it is better to look for an alternative in either a cube/dimension design or even further, in the dimensional model. The general rule of thumb is to always prefer a built-in Analysis Services feature over writing MDX. This was the first recipe in a series of recipes that showed how. The others follow, so read on.

Typical scenarios

Every time you catch yourself using functions such as `Except()` or `Filter()`, too often in your calculations, you should step back and consider whether that's a repeating behavior and whether it would pay off to have an attribute to separate the data you've been separating using MDX calculations. If it has a repeating pattern and it's not something unpredictable, there's your candidate.

Once you have a member (or more) separating two or more parts of the set, you can simply use them in the calculations. You can even call upon their children or other descendants. You could make ratios the easier way. Everything becomes simplified.

Using a distinct count measure to implement histograms over existing hierarchies

Histograms are an important tool in data analysis. They represent the distribution of frequencies of an entity or event. In OLAP, those terms translate to dimensions and their attributes.

This recipe illustrates how to implement a histogram over an attribute `Color`. The histogram needs to tell us the product count for each `Color` in each `Fiscal Year`.

In order to create a histogram, we need a measure that can count distinct members of an attribute for any given context.

There are two solutions to this problem. One is to use a calculated measure; the other is to use a regular measure with the distinct count type of the aggregation.

Many BI developers might lean towards the first option. The calculated measure might be an easy-to-implement solution because deploying the MDX script doesn't require reprocessing the cube.

As with most things in life, a shortcut is usually not an optimal solution. Depending on various factors like the cube and dimension sizes, the calculation can turn out to be slow in certain scenarios or contexts.

The second option of creating a `Distinct` count type of measure is a better choice in terms of performance. In this recipe, we will discuss how to implement an attribute-based histogram using the second option, that is, to create a `Distinct` count type of measure over a dimension key column in the fact table.

Getting ready

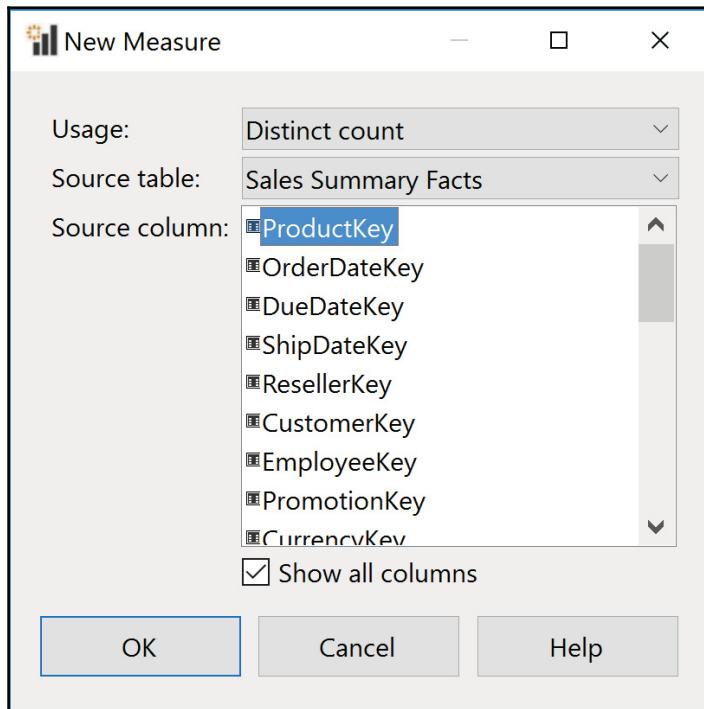

Open the SQL Server Data Tools (SSDT) and then open the Adventure Works DW 2016 solution. Once it loads, double click on the **Adventure Works** cube.

In this example we're going to analyze products based on their characteristics. We're going to show how many red, green, and blue products are present in a particular subcube.

How to do it...

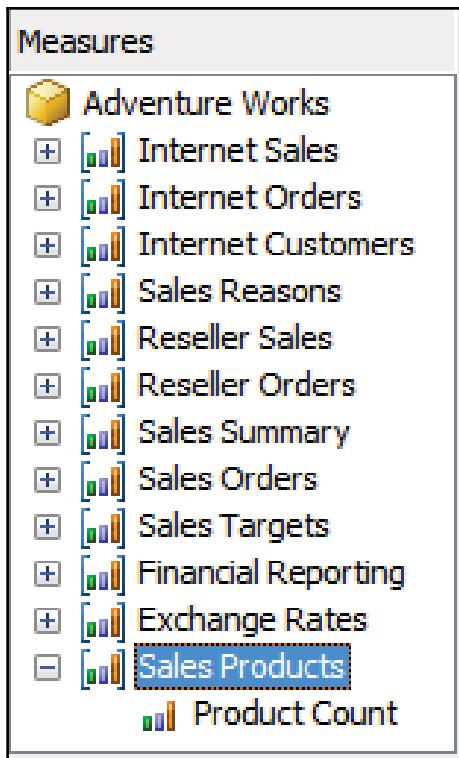

Follow these steps to create a **Distinct count** measure:

1. Create a new **Distinct count** type of measure using the column `ProductKey` in the **Sales Summary Facts** table. You need to right-click on the cube name, **Adventure Works**, and then choose **New Measure...**

2. Name it `Product Count` and set the format string as `#, #` (without quotes) in the **Properties** pane.

3. The best practice for distinct count measures is to have them in a separate measure group. Notice how SSDT ensures this is done. Name the new measure group **Sales Products**.

4. Process the cube. Once it's done, go to the **Cube Browser** tab and reconnect. Click on the **Analyze in Excel** icon on top to open Excel.
5. Test this new measure using any attribute of the Product dimension or any other dimension; for example, the Date dimension as seen in the following screenshot. The measure aggregation function adjusts itself returning the distinct number of products in each cell:

	A	B	C	D	E	F	
1	Product Count	Fiscal Year	▼				
2	Row Labels	▼	FY 2010	FY 2011	FY 2012	FY 2013	Grand Total
3	Black		19	71	87	34	111
4	Blue		1	2	27	23	28
5	Multi		4	11	12	5	16
6	NA			12	45	31	47
7	Red		26	45	23	4	50
8	Silver		8	14	36	28	44
9	Silver/Black				7	7	7
10	White		2	2	2	2	4
11	Yellow			9	43	32	43
12	Grand Total		60	166	282	166	350

How it works...

Attribute-based histograms are relatively easy to implement. All we need is a `Distinct` count type of measure over a dimension key column in the fact table. After that, everything is pretty straightforward; the new measure reacts to every attribute, directly or indirectly related to that fact table.

There's more...

Here's the calculation that can produce the same result as the `Distinct` count type of measure we have implemented in this recipe:

```
Create MEMBER CurrentCube.[Measures].[Product Count calc orig] AS
    Count( EXISTING
        Exists( [Product].[Product].[Product].MEMBERS, ,
            'Sales Summary' ) )
    , Visible = 0
    , Format_String = '#,#'
    , Associated_Measure_Group = 'Sales Summary'
    , Display_Folder = 'Histograms'
;
Create MEMBER CurrentCube.[Measures].[Product Count calc] AS
    iif( [Measures].[Product Count calc orig] = 0, null,
        [Measures].[Product Count calc orig] )
```

```
, Format_String = '#,#'  
, Associated_Measure_Group = 'Sales Summary'  
, Display_Folder = 'Histograms'  
;
```

What we're doing here is creating two calculated measures. One, hidden, returns the count of products relevant to the existing context which have data in the Sales Summary measure group. The other, visible, converts zeros to null because the result of the first calculated measure is never null and we don't want zeros in our result. We'd like to keep the data sparse.

As we have mentioned in the introduction, a calculated measure might be easy to implement, but a regular measure offers better performance, especially in very large dimensions. In scenarios where the distinct count column (`ProductKey`) has millions of distinct values, a distinct count measure may be a much, much faster solution than an MDX calculation.

We should also keep in mind that an additional measure does come at the cost of having to process and store it.

In scenarios where `ProductKey` has few distinct values (that is, 100,000 members or less), another good approach might be to build a `ProductKey` grain measure group and add a many-to-many relationship on all the other dimensions in the Sales Summary measure group. Essentially, any distinct count can be reformulated as a many-to-many relationship which is explained in detail in Marco Russo's, Many-to-Many Dimensional Modeling paper: <http://tinyurl.com/M2Mpaper>.

See also

- The next recipe, *Using a dummy dimension to implement histograms over nonexisting hierarchies*, covers a similar topic

Using a dummy dimension to implement histograms over nonexistent hierarchies

As seen in the previous recipe, Analysis Services supports attribute-based histograms by design. All it takes is a distinct count measure and we're good to go.

This recipe illustrates how to implement a more complex type of histograms over nonexistent hierarchies.

The complexity comes from the fact that the hierarchy which we'd like to base the calculation on does not exist. That's a big issue where a multidimensional cube is concerned.

OLAP cubes operate on predetermined structures. It is not possible to build items on the fly. In other words, it is not possible to create a new hierarchy based on a calculation and use it the way we would use any other hierarchy. In OLAP, every hierarchy must be prepared in advance and must already be a part of the cube, otherwise it can't exist.

In this recipe, we're interested in the fact table. The **fact table** represents a series of events that are taking place and are being recorded in a very consistent manner. Every row tells a story of an event. Various columns in that row represent dimensions related to those events.

In the previous recipe, where we calculated histograms over attributes, we created a measure based on one of the dimension columns in the fact table. That measure counted distinct dimension member keys that occur in a part of the fact table, the part determined by other dimensions in context. Those other dimensions limit the size of the fact table, acting like a filter to it.

This time we're interested in something else. We're interested in combining several dimensions, for example counting the number of the distinct members of one of those dimensions inside the other.

Let's illustrate this with an example. Take resellers and their orders. We might be interested in orders only, as in the number of orders a particular reseller made in a certain period. The possible values are 0, 1, 2, 3, and so on, up to the maximum number of orders a single reseller ever made. If we want to analyze that, then that's a measure, the `Reseller Order Count` measure in the Adventure Works cube, to be precise. Resellers are simply a dimension we want to use on an axis in this case.

But what if we want to analyze both the resellers and the orders but neither of them are in the rows or columns? That's a different story. For example, we want to know how many resellers made 0 orders in a given time frame, how many of them made 1, 2, or more. That sequence of numbers (0, 1, 2, and so on) is what should go in the rows (or columns), something we will iterate on. The measure in this case would be the `Reseller Count` measure, a measure showing the distinct count of resellers in a particular context. The only problem is, neither this special dimension nor the distinct count measure exists. .

While it is relatively easy to make a distinct count type of measure, either using a calculated measure or a regular measure with the distinct count aggregation, creating a dimension takes preparation and cannot be done on the fly.

Now that we've explained the problem, let's see how it can be solved.

Getting ready

Open the SQL Server Data Tools (SSDT) and then open the Adventure Works DW 2016 solution. Once it loads, double-click on the **Adventure Works DW** data source view.

In this example, we're going to analyze resellers based on the frequency of their orders. In other words, we're going to show how many resellers made zero, one, two, three, and so on orders in a given time frame and for given conditions.

How to do it...

Follow these steps to implement the histogram over the hierarchy that doesn't exist in the cube:

1. Create a new named query `Reseller Order Frequency` with the following definition:

```
SELECT 0 AS Interval  
UNION ALL  
SELECT
```

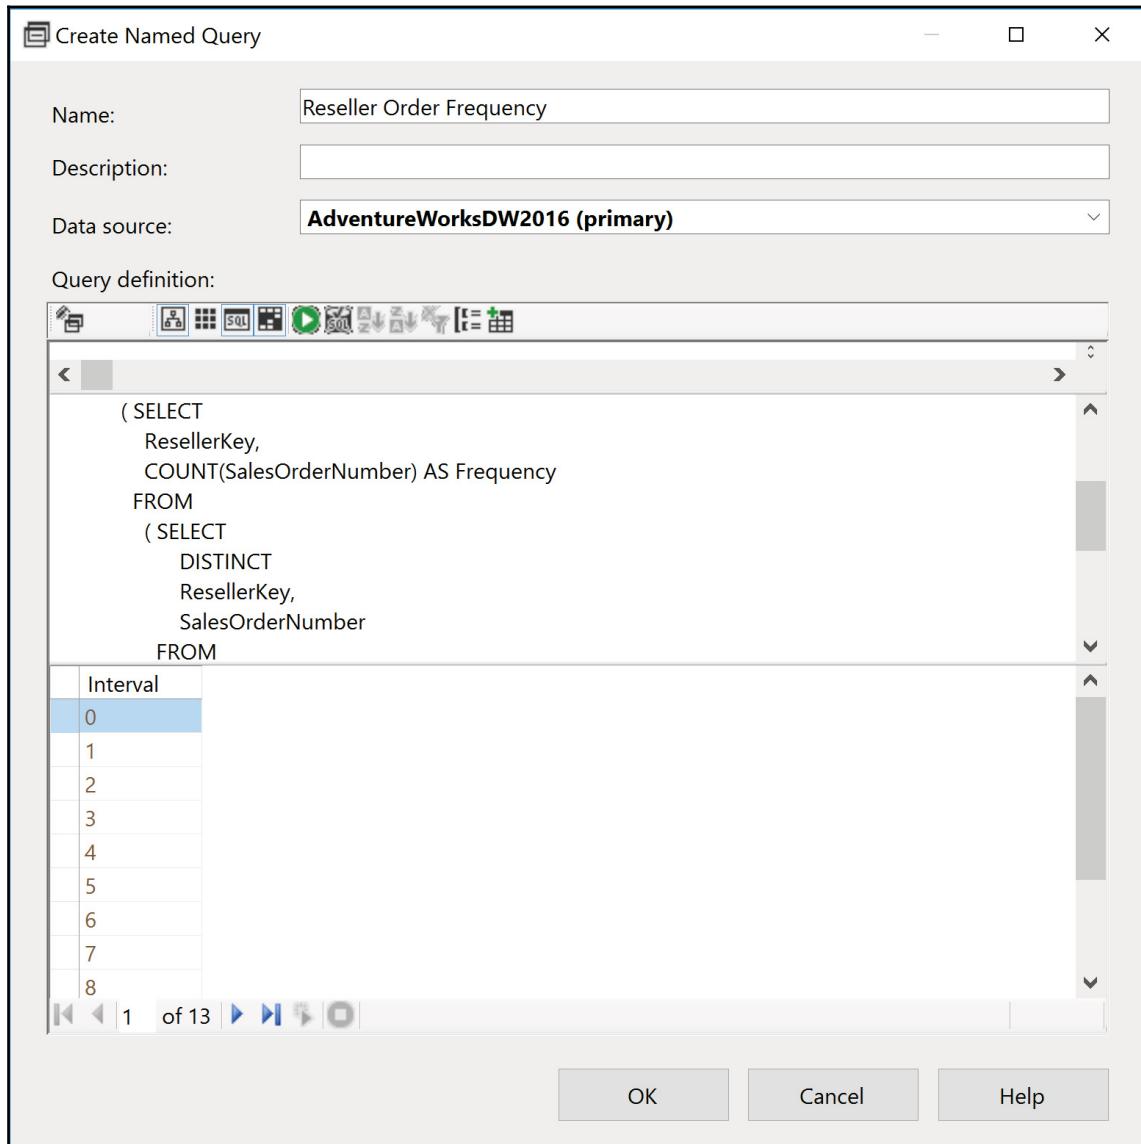

```
TOP (
    SELECT
        MAX(Frequency) AS Interval
    FROM
        ( SELECT
            ResellerKey,
            COUNT(SalesOrderNumber) AS Frequency
        FROM
            ( SELECT
                DISTINCT
                ResellerKey,
                SalesOrderNumber
            FROM
                dbo.FactResellerSales
            ) AS t1
        GROUP BY
            ResellerKey
        ) AS t2
    ) ROW_NUMBER()
    OVER (ORDER BY ResellerKey) AS Interval
)
FROM
    dbo.FactResellerSales
```

2. Turn off the **Show/Hide Diagram Pane** and **Show/Hide Grid Pane** and execute the previous query in order to test it.

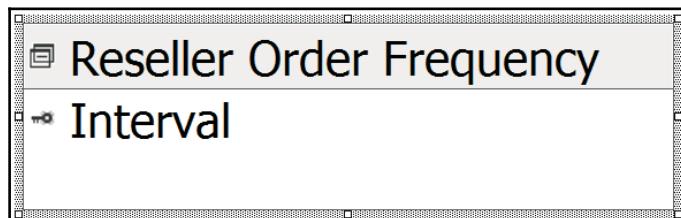

An error might pop up when you run this type of query or when you open the named query to change it. The error basically says that this type of query cannot be represented visually using the diagram pane because it contains the `OVER` SQL clause. That's the reason why we've turned that pane off. If, for whatever reason, you see that error anyway, just acknowledge it and continue with the recipe. It is merely information, not a problem.

3. Once executed, the query returns 13 rows with numbers, the first one being zero and the last one being the maximum number of orders for a customer (here 12).

4. Close the named query editor, locate the Reseller Order Frequency named query, and mark the **Interval** column as a **Logical Primary Key**.

5. Create a new dimension using the previously defined named query and name it Reseller Order Frequency.
6. Use the **Interval** column for both the **KeyColumn** and the **ValueColumn** properties:

The screenshot shows the Windows Properties dialog box for the "Interval" dimension attribute. The "ValueColumn" property is highlighted in blue, displaying the value "Reseller Order Frequency.Interval (BigInt)". A tooltip below the dialog explains what the ValueColumn property does.

NamingTemplate	
RootMemberId	ParentIsBlankSelfOrMissing
UnaryOperatorColumn	(none)
Source	
CustomRollupColumn	(none)
CustomRollupPropertiesColumn	(none)
KeyColumns	Reseller Order Frequency.Interval (BigInt)
NameColumn	(none)
ValueColumn	Reseller Order Frequency.Interval (BigInt) ...

ValueColumn
Specifies the details of the binding to the column containing the member value.

7. Process in full that dimension.
8. Name the All member All Intervals.
9. Open the **Adventure Works** cube and add that dimension without linking it to any measure group.

10. Deploy the changes by right-clicking on the project name (in the **Solution Explorer** pane) and by choosing **Deploy action**. Then choose the **Process** action to process the cube.
11. Go to the Calculations tab and add the following code to the end of the MDX script:

```
Create MEMBER CurrentCube.[Measures].[RO Frequency] AS
    Sum( EXISTING [Reseller].[Reseller].[Reseller].MEMBERS,
        iif( [Reseller Order Frequency].[Interval]
            .CurrentMember.MemberValue =
            [Measures].[Reseller Order Count],
            1,
            null
        )
    )
    , Format_String = '#,#'
    , Associated_Measure_Group = 'Reseller Orders'
    , Display_Folder = 'Histograms'
;

Scope( ( [Measures].[RO Frequency],
    [Reseller Order Frequency].[Interval].[All Intervals] ) );
    This = Sum( [Reseller Order Frequency].[Interval]
        .[Interval].MEMBERS,
        [Measures].[RO Frequency]
    );
End Scope;
```

12. Deploy the solution.
13. Go to the **Cube Browser** tab and click on the **Analyze in Excel** icon on top to open Excel to build a pivot using the new RO Frequency measure. Then place the Reseller Order Frequency dimension on the opposite side from the measures, on the rows. Finally, add another dimension to the columns, the Date dimension, to test if the calculation works for hierarchies on both axes. As seen in the following screenshot, values don't repeat, which is a sign that our calculation works. They represent the number of resellers who in a particular time period (years, in this case) made as many orders as shown in the hierarchy on the rows. The distribution of customers and their orders is in fact the histogram we've been looking for:

	A	B	C	D	E	F	G	H
1	RO Frequency	Fiscal Year						
2	Row Labels	FY 2009	FY 2010	FY 2011	FY 2012	FY 2013	FY 2014	Grand Total
3	0	701	500	284	146	240	701	66
4	1		74	42	61	124		30
5	2		127	199	211	335		20
6	3			68	67	2		38
7	4			86	214			235
8	5			2	2			20
9	6			20				21
10	7							34
11	8							145
12	9							10
13	10							8
14	11							10
15	12							64
16	Grand Total	701	701	701	701	701	701	701

How it works...

There are several important things in this recipe. We'll explain them one by one.

The solution starts with a particular T-SQL query that was used as a named query in the data source view. The purpose of that query is to return the maximum number of orders for any customer and all the integers up to that number, starting from zero.

The maximum frequency number is obtained by combining the distinct occurrence of the ResellerKey and SalesOrderNumber columns in the ResellerSales fact table and by taking the count of the orders for each reseller. That's the essence of that query.

As we saw, the query returns 13 rows, with numbers starting from zero and ending with 12. Those values in turn become members of a new dimension which we'll build afterwards. The dimension is in no way associated with any fact table or dimension in that cube. What's the purpose then?

We should remember that our initial goal is to show how many distinct customers fall into each segment: zero orders, one order, two orders, and so on. That requirement is contradictory in OLAP terms because it would require two measures: one with the distinct number of customers and the other with the distinct number of orders, both somehow used one against the other in a pivot. The problem is that OLAP supports measures on one axis only. Actually, that's true for any hierarchy.

So, what's the solution?

The idea is to build a special dimension and use it on one axis while we're keeping the other measure on another axis. The only thing this dimension has to have is a sequence of numbers so that we can assign values to them, somehow.

Now we've come to the calculations: the MDX script.

The first part of the calculation is the main part. That's where the assignment takes place. The idea is to use the `MemberValue` property value of the current member of the `Reseller OrderFrequency` dimension and increment the `RO Frequency` measure only when `MemberValue` equals the number of orders a particular reseller made in the current slice. In other words, we're descending to the granularity of the resellers where we're counting how many of them are equal to the condition. The condition says that the number of orders must match the utility dimension member's value we're currently on. That way each reseller is thrown in one of the buckets, one of the members of that new dimension. Once we're done with the process, each bucket tells us how many resellers made that many orders. In other words, we have a complex histogram, a histogram based on an up-to-now non-existent dimension.

Each member of the utility dimension got its value using the techniques described earlier except for the `All` member. No value was assigned to it because the calculation operated only on individual members. That's why there was a requirement to use another statement where we're basically saying, *Collect all the individual values obtained during the allocation process and aggregate them.*

There's more...

The example presented here used a dedicated utility dimension named `Reseller Order Frequency`. It had exactly 13 members. However, they were not fixed; they were the consequence of the data in the fact table. This means that the number of members can grow with time. It will always be a sequence of natural numbers up to the maximum number of occurrences for the entire fact table.

It is quite reasonable to expect multiple event-based histograms in the same cube. One way to handle this would be to build a separate named query for each combination of dimensions we'd like to analyze, each returning different number of rows which are eventually translated to dimension members. But there's another approach to it.

It is possible to build a single utility dimension which contains enough members so that it can cover any, or most, types of histograms. The idea is to build the tally table – a table with numbers starting from zero and ending with some big number. How big depends on your preference, it could be 100, 1,000, or more.

The name of the corresponding dimension should be unique, something neutral like the Frequency dimension.

The code presented in this recipe applies, but it must be modified to include the new dimension name. It can be repeated many times, once for each new distinct count type measure.

The only downside is that we have more members now than before, for a particular distinct count type measure. The query results and charts might look bad because of this. For example, if the dimension contains 100 members and we only have 13 frequencies like in the example presented in this recipe, most of the cells would be empty.

Turning the NON EMPTY switch wouldn't help either. It would only do damage by removing some of the members in the range. What we need is a list of numbers starting from zero and ending with the maximum value. If some of the members inside that range are empty, they must be preserved. The idea is to show the full range, and not shrink it into something more compact by removing empty values.

How can we solve this problem?

There are several solutions. One is to use the named sets defined in the MDX script defined as a range, with 0 as the maximum. Here's an example:

```
Create SET CurrentCube.[RO Frequency Set] AS
    { null : Tail( NonEmpty( [Frequency]
        .[Interval].[Interval].MEMBERS,
        [Measures].[RO Frequency] ),
        1 ).Item(0)
```

In some tools, the set can be used on the rows or columns instead of the complete Frequency dimension.

The other solution is to provide another scope in which you would convert nulls into zeros for members that form the range. Others would be null. That solution would work with `NON EMPTY` then.

DSV or DW?

The initial T-SQL query could have been implemented in the relational DW database instead. After all, it is the best practice to keep everything related to business logic in one place and that place is the Data Warehouse (DW). However, the concept of the utility dimension is purely SSAS-related and hence falls in the domain of a BI developer, not a DW developer. He's the one who creates it, knows what it's for, and modifies it when required. That's the reason we've used the Data Source View (DSV) instead. Does it have to be DSV then? No, it is up to you to decide which view is better for your situation. Just be consistent.

More calculations

Here's another calculation you may consider helpful. It calculates the percentage in total:

```
Create MEMBER CurrentCube.[Measures].[RO Frequency Total] AS
    ( [Measures].[RO Frequency],
      [Reseller Order Frequency].[Interval].DefaultMember )
    , Visible = 0
    , Format_String = '#,#'
    , Associated_Measure_Group = 'Reseller Orders'
    , Display_Folder = 'Histograms'
;

Create MEMBER CurrentCube.[Measures].[RO Frequency %] AS
    iif( [Measures].[RO Frequency Total] = 0,
        null,
        [Measures].[RO Frequency] /
        [Measures].[RO Frequency Total]
    )
    , Format_String = 'Percent'
    , Associated_Measure_Group = 'Reseller Orders'
    , Display_Folder = 'Histograms'
;
```

The result looks like this:

1	Business Type	Value Added				Total RO	Total RO		
			Shop		Reseller				
			Interval	RO Frequency	RO Frequency %	RO Frequency	RO Frequency %	RO Frequency %	
4	0	31	13.42%	22	9.24%	13	5.60%	66	9.42%
5	1	13	5.63%	11	4.62%	6	2.59%	30	4.28%
6	2	8	3.46%	7	2.94%	5	2.16%	20	2.85%
7	3	14	6.06%	14	5.88%	10	4.31%	38	5.42%
8	4	71	30.74%	76	31.93%	88	37.93%	235	33.52%
9	5	6	2.60%	7	2.94%	7	3.02%	20	2.85%
10	6	10	4.33%	3	1.26%	8	3.45%	21	3.00%
11	7	10	4.33%	12	5.04%	12	5.17%	34	4.85%
12	8	44	19.05%	50	21.01%	51	21.98%	145	20.68%
13	9	1	0.43%	5	2.10%	4	1.72%	10	1.43%
14	10	1	0.43%	4	1.68%	3	1.29%	8	1.14%
15	11	5	2.16%	1	0.42%	4	1.72%	10	1.43%
16	12	17	7.36%	26	10.92%	21	9.05%	64	9.13%
17	Grand Total	231	100.00%	238	100.00%	232	100.00%	701	100.00%

As you can see, calculations work for other dimensions as long as they are related to the measure group of the Reseller Order Count measure, the measure used in the calculations.

Other examples

The following is a link to a page describing the same thing in another way: <http://tinyurl.com/OLAPHistograms>.

- The recipe *Using a distinct count measure to implement histograms over existing hierarchies* covers a similar topic. *Creating a physical measure as a placeholder for MDX assignments* is directly related to this recipe and has an improved version of MDX assignments presented in this recipe.

Creating a physical measure as a placeholder for MDX assignments

There can be many problems regarding calculated members. First, they don't aggregate up like regular members; we have to handle that by ourselves. Next, the drill through statements and security restrictions are only allowed for regular members. Not to mention the limited support for them in various client tools, such as Excel. Finally, regular measures often noticeably beat their calculate measures counterparts in terms of performance or the ability to work with the subselect.

On the other hand, calculated members can be defined and/or deployed very easily. They don't require any drastic change of the cube or the dimensions and therefore are good for testing, debugging, as a temporary solution, or even as a permanent one. Anything goes as long as they don't become a serious obstacle in any of the ways mentioned earlier. When that happens, it's time to look for an alternative.

In the previous recipe, *Using a dummy dimension to implement histograms over nonexisting hierarchies*, we used the EXISTING operator in the assignment made for the calculated measure RO_Frequency. First, that expression tends to evaluate slowly which becomes noticeable on large dimensions. The Reseller dimension is not a large dimension and therefore, the provided expression will not cause significant performance issues there. However, the second problem is that the EXISTING operator will not react to the subselect and will therefore evaluate incorrectly if the subselect is used. That might become an issue with tools like Excel that extensively use the subselect whenever multiple members are selected in the filter area.

This recipe illustrates the alternative approach. It shows how a dummy physical measure can be used as a placeholder for calculations assigned to a calculated measure. In other words, how a calculated measure can be turned into a regular measure to solve a particular problem. As explained a moment ago, subselect is just one of the reasons we look for the alternative, which means the idea presented in this recipe can be applied in other cases too.

Getting ready

This recipe depends heavily on the previous recipe; therefore you should implement the solution it presents. If you have read and practiced the recipes sequentially, you're all set. If not, simply read and implement the solution explained in the previous recipe in order to be able to continue with this one.

Once you have everything set up, you're ready to go with this one.

How to do it...

Follow these steps to implement a physical measure as a placeholder for MDX assignments:

1. Double-click on the **Adventure Works DW** data source view in the **Adventure Works DW 2016** solution opened in the **SQL Server Data Tools** (SSDT).
2. Locate the **Reseller Sales Fact** table in the pane with the list of tables on the left side.
3. Right-click it and add a new column by selecting the **New Named Calculation** option.
4. The definition of the column should be:

```
CAST( null AS int )
```
5. Name the column **NullMeasure**. Save the data source view.
6. Double-click on the **Adventure Works** cube and locate the **Reseller Sales** measure group.
7. Add a new physical measure in that measure group using the newly-added column in the underlying fact table and name it **RO Frequency DSV**.
8. Specify **Histograms** for its **DisplayFolder** property and provide **#, #** for the **FormatString** property.
9. Use the **Sum** for the **AggregateFunction** and set the **NullProcessing** property (available inside the **Source** property) to **Preserve**.
10. Deploy the changes. Process the **Adventure Works** cube.

11. Go to the **Calculations** tab and provide the adequate scope statement and MDX assignment for the new regular measure:

```
Scope( [Measures].[RO Frequency DSV],  
      [Reseller Order Frequency].[Interval].[Interval].Members,  
      [Reseller].[Reseller].[Reseller].Members  
    );  
This = iif( [Reseller Order Frequency].[Interval]  
           .CurrentMember.MemberValue =  
           [Measures].[Reseller Order Count],  
           1,  
           null  
         );  
End scope;
```

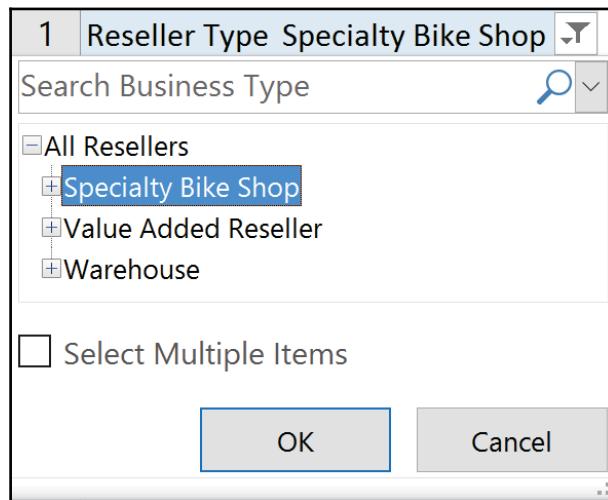

12. The Reseller Order Frequency dimension is not related to any fact table and automatic aggregations cannot work. Because of this, we have to perform additional steps, including providing the assignment for the All member of the dummy dimension Reseller Order Frequency:

```
Scope( [Measures].[RO Frequency DSV],  
      [Reseller Order Frequency].[Interval].[All Intervals]  
    );  
This = Sum( [Reseller Order Frequency].[Interval]  
           .[Interval].MEMBERS,  
           [Measures].[RO Frequency DSV]  
         );  
End Scope;
```

13. Deploy the changes made in the MDX script.
14. Now, go to the **Cube Browser** tab. Open **Excel** by clicking on the **Analyze in Excel** icon on top to build a pivot using the Reseller Order Frequency dimension on the rows and both the new **RO Frequency DSV** measure and the old one, the **RO Frequency** measure on the columns:

	A	B	C
1	Interval	RO Frequency	RO Frequency DSV
2	0	66	66
3	1	30	30
4	2	20	20
5	3	38	38
6	4	235	235
7	5	20	20
8	6	21	21
9	7	34	34
10	8	145	145
11	9	10	10
12	10	8	8
13	11	10	10
14	12	64	64
15	Grand Total	701	701

15. As you can see in the preceding screenshot, the calculation works.
16. Now, add the **Business Type** attribute hierarchy of the **Reseller** dimension in the report filer area, and select **Specialty Bike Shop** for the **Filter Expression** there. The following screenshot shows how to select the filter:

17. This screenshot shows the result with the report filter.

	A	B	C
1	Reseller Type	Specialty Bike Shop	▼
2			
3	Interval	RO Frequency	RO Frequency DSV
4	0	31	31
5	1	13	13
6	2	8	8
7	3	14	14
8	4	71	71
9	5	6	6
10	6	10	10
11	7	10	10
12	8	44	44
13	9	1	1
14	10	1	1
15	11	5	5
16	12	17	17
17	Grand Total	231	231

18. Notice that the values for both the RO Frequency DSV measure and the RO Frequency measure adjusted to the new context.
19. Next, we are going to write a MDX query with explicit subselect to prove that the RO Frequency DSV measure will adjust to the new context and the RO Frequency measure will not.
20. In the following MDX query, we put the Business Type filter in the subselect on purpose. We will prove that calculated measures using the EXISTING keyword will not respond to subselect, and physical measures will respond to subselect.

```
SELECT
  { [Measures].[RO Frequency],
    [Measures].[RO Frequency DSV]
  } ON 0,
  [Reseller Order Frequency].[Interval].[Interval] ON 1
FROM
```

```
(  
    SELECT  
        [Reseller].[Business Type].&[Specialty Bike Shop] ON  
0  
    FROM  
        [Adventure Works]  
)
```

21. Execute the preceding query, and the result should look like the following screenshot:

	RO Frequency	RO Frequency DSV
0	66	31
1	30	13
2	20	8
3	38	14
4	235	71
5	20	6
6	21	10
7	34	10
8	145	44
9	10	1
10	8	1
11	10	5
12	64	17

22. Notice that the values for the RO Frequency DSV adjusted to the new context in subselect while the values of the RO Frequency measure (highlighted in the screenshot) remained unchanged. The alternative approach with a physical measure worked!

How it works...

A column, defined with the value of null, is created in the fact table and later used as a new cube measure. By default, the Analysis Service would turn the value of null into zero; however, we have prevented that by providing the `Preserve` option in the `NullProcessing` property. This produced a regular measure that is always null in any context.

Now let's take a look at the definition of the measure from the previous recipe and see how it changed the adequate scope statement. We'll repeat them here.

The calculated measure from the previous recipe is defined like this:

```
Create MEMBER CurrentCube.[Measures].[RO Frequency] AS
    Sum( EXISTING [Reseller].[Reseller].[Reseller].MEMBERS,
        iif( [Reseller Order Frequency].[Interval]
            .CurrentMember.MemberValue =
            [Measures].[Reseller Order Count],
            1,
            null
        )
    )
    , Format_String = '#,#'
    , Associated_Measure_Group = 'Reseller Orders'
    , Display_Folder = 'Histograms'
;
```

The new measure from this recipe is scoped like this:

```
Scope( [Measures].[RO Frequency DSV],
    [Reseller Order Frequency].[Interval].[Interval].Members,
    [Reseller].[Reseller].[Reseller].Members
);
This = iif( [Reseller Order Frequency].[Interval]
    .CurrentMember.MemberValue =
    [Measures].[Reseller Order Count],
    1,
    null
);
End scope;
```

Notice the important difference in them. In our new physical measure implementation, we first passed the burden of detecting existing resellers to the server by adding the set of resellers inside the definition of the scope. We also passed the burden of summarizing the values across the existing resellers to the server. In other words, the server does all the heavy work for us. Another benefit we get from using a dummy regular measure is that the calculation will also work with the subselect, as shown in the example.

There's more...

However, the improvement comes with a price. In this case it is manifested in the form of all the modifications you have to perform and maintain later, as well as the increased cube size because of the new measure. Because of that, it is up to you to decide whether it pays off to implement this alternative or not in your particular case. Hopefully you'll have the chance to test it in parallel to the existing solution and measure the costs/benefits ratio of the new solution.

Additional information can be found in Teo Lachev's article: <http://tinyurl.com/TeoCalcAsRegular>.

Associated measure group

The same format string and display folder used for the calculated measure can be specified in the process of creating the new measure. The only exception we made is that we used the `Reseller Sales` measure group. That's because the `Reseller Orders` measure group, the one which the calculated measure was associated with, has a distinct count measure and distinct count measures should not be mixed with other regular measures.

We've decided to put the calculated measure in the best place we thought it should be. It made sense to put it in the same measure group as the `Reseller Orders Count` measure because they both count something related to resellers. Just for the record, we could have easily defined it on any measure group, it wouldn't make much difference.

See also

- Reading and implementing the recipe, *Using a distinct count measure to implement histograms over existing hierarchies* is a prerequisite for this recipe

Using a new dimension to calculate the most frequent price

In this recipe, we're going to analyze the products and their prices. The requirement is to find the most frequent price, or Mode Price, in any context.

Finding the price for a particular product doesn't look like a problem. We can either read it in its properties if the price is available as a product member property, or we can calculate the average price based on the sales amount and the quantity sold.

Member properties are static and therefore choosing the first approach would be wrong. For example, the price in the form of the member property doesn't change in time or with the territory. What we need is a dynamic expression.

The other option is to calculate the average price, but that's also not good enough. We need to know the exact price for each transaction, not the average value.

If we go low enough with the granularity of the query, the average price will eventually become the price used in the transaction; however, cubes are not optimized to be queried on the leaf level. All in all, it's pretty obvious we need some help here. This can't be solved in MDX alone.

The solution is to create a new dimension based on the price column in the fact table. That way we can have prices as an object we can use and manipulate within MDX calculations.

In addition to that, we need a measure that counts rows, but that's already there (or can be easily added) in every measure group (as long it's not the one with the distinct count measure). That measure can be used to isolate the price with the maximum number of rows for a given context. After that, we need to extract this price member's value which becomes the price we're after.

Let's see how it's done in this recipe.

Getting ready

Open the SQL Server Data Tools (SSDT) and then open the Adventure Works DW 2016 solution. Once it loads, double-click on the **Adventure Works DW** data source view.

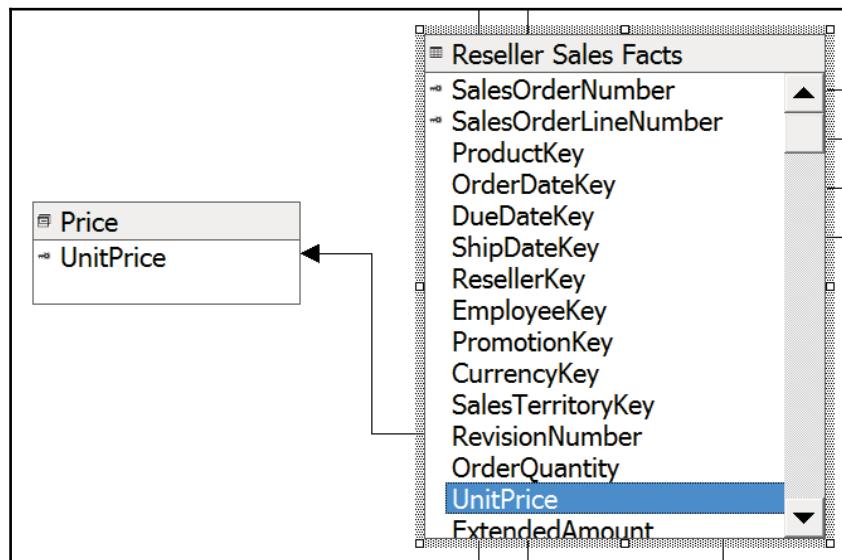

How to do it...

Follow these steps to change the model the cube is built from which in turn will enable simple and effective MDX calculations:

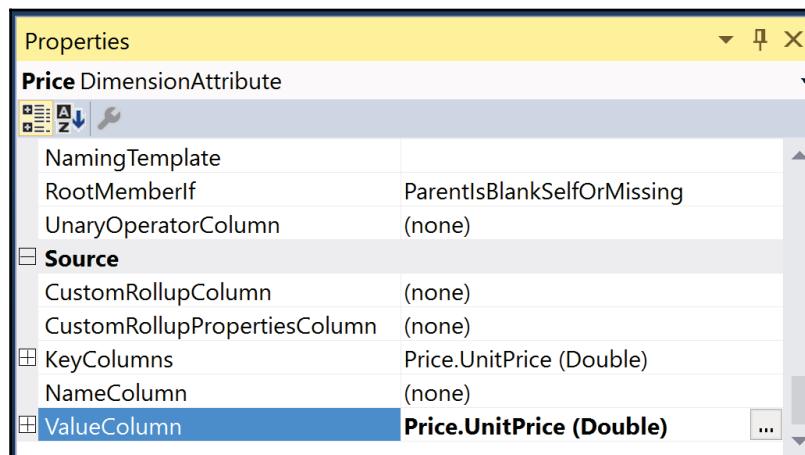

1. Create a new named query. Name it `Price` and use the following definition for it:

```
SELECT  
    DISTINCT  
    UnitPrice  
FROM  
    dbo.FactResellerSales
```

2. Execute the query in order to test it. It should return 233 rows.
3. Make sure you've selected the single column `UnitPrice` in that table and then mark it as a `Logical Primary Key`.
4. Locate the `Reseller Sales` diagram in the **Diagram Organizer** pane.
5. Drag and drop the `Price` named query in the free area of that diagram and link the **Reseller Sales Facts** fact table to it using the `UnitPrice` columns in both objects. The following screenshot shows the relation in the DSV.

6. Create a new dimension using the previously defined `Price` named query and name it `Price`.
7. Use the `UnitPrice` column for the `KeyColumn`.
8. Name the attribute `Price`.
9. Once you finish with the wizard, the **Dimension Editor** will look like the following screenshot:

10. Verify that the `OrderBy` property is set to `Key`.
11. Set the `ValueColumn` to `UnitPrice` column.
12. Name the `All` member `All Prices`.
13. Process the dimension in full.
14. When it's done, verify the dimension in the **Browser** tab of the **Dimension Editor**. The prices should be sorted in ascending order.
15. Now, open the **Adventure Works** cube and go to the **Dimension Usage** tab of the cube to add the `Price` dimension.
16. Once added, the dimension will be automatically related to two measure groups: `Reseller Sales` and `Reseller Orders`. Verify that and then set its `Visible` property to `False` in the **Properties** pane.
17. Deploy the changes and process the cube. When the processing is over, you're ready to write calculations.
18. Go to the **Calculations** tab and position the cursor in the end of the MDX script.

19. Enter the calculation for the Mode Price:

```
Create MEMBER CurrentCube.[Measures].[Mode Price] AS
    iif( IsEmpty( [Measures].[Reseller Transaction Count] ),
        null,
        TopCount( [Price].[Price].[Price].MEMBERS,
            1,
            [Measures].[Reseller Transaction Count]
        ).Item(0).MemberValue
    )
    , Format_String = 'Currency'
    , Display_Folder = 'Statistics'
    , Associated_Measure_Group = 'Reseller Sales';
```

20. Deploy the changes in the MDX script and then go to the **Cube Browser** tab. Open Excel by clicking on the **Analyze in Excel** icon on top.
21. A comparison of the **Mode Price** and the **Reseller Average Unit Price** measures across the products subcategories can be seen in the following screenshot:

	A	B	C
	Reseller Average		
1	Product Categories	Unit Price	Mode Price
2	Accessories	\$21.67	\$20.19
3	Bikes	\$882.72	\$469.79
4	Mountain Bikes	\$1,085.21	\$647.99
5	Road Bikes	\$779.14	\$469.79
6	Touring Bikes	\$841.25	\$1,430.44
7	Clothing	\$28.21	\$28.84
8	Components	\$251.40	\$202.33
9	Bottom Brackets	\$56.39	\$72.89
10	Brakes	\$63.88	\$63.90
11	Chains	\$12.14	\$12.14
12	Cranksets	\$179.76	\$242.99
13	Derailleurs	\$61.36	\$54.89
14	Forks	\$117.43	\$137.69
15	Handlebars	\$44.73	\$33.77
16	Headsets	\$59.78	\$74.84
17	Mountain Frames	\$432.37	\$158.43
18	Pedals	\$37.35	\$48.59
19	Road Frames	\$335.10	\$202.33
20	Saddles	\$26.17	\$31.58
21	Touring Frames	\$425.50	\$602.35
22	Wheels	\$127.53	\$67.54
23	Grand Total	\$444.43	\$469.79

How it works...

By counting rows in the original fact table we're basically saying we want to know how many times the current price occurred in the context of other dimensions. That, of course, demands for the `Price` dimension which we have made in the initial steps of the solution presented in this recipe.

There's something else to it. The `Price` dimension is kept aside all the time by being invisible. Its only purpose is to spread the prices so that we can pick the most frequent one. The evaluation of the most frequent price is done in the definition of the calculated measure, where we're applying the `TopCount()` function over all prices and therefore use the `Reseller Transaction Count` measure to count how many occurrences each price had in the given context. For the record, the `Reseller Transaction Count` measure is also invisible, but it can be used in the calculations.

If you want to verify the correctness of the calculation, make both the `Price` dimension and the `Reseller Transaction Count` measure visible, deploy the changes, and use them in the pivot. The price with the highest value of the `Reseller Transaction Count` measure is automatically selected as the **Mode Price**.

In the end, it's worth mentioning that once we had the most frequent price, we read its member value and showed it as the result of the calculation.

There's more...

It's perfectly normal to encounter situations where two or more prices have the same frequency, the same rate of occurrence. However, the calculation we made can take only a single one. How do we know which one?

Unlike datasets resulting from queries in the relational world, the default behavior of sets in the multidimensional world is that they are always sorted unless explicitly requested otherwise. The order is determined during the design of the dimensions. Each attribute has a property for that. It can be a `Key`, `Name`, or another attribute. The point is, members are sorted one way or the other.

Because of this, in the case of a tie, the order of members determines the winner. If members are sorted by the key, a member with the lower key will win. If members are sorted by a name, the one that alphabetically comes sooner wins. If you need the opposite order, consider using another attribute or switch the keys to their negative values.

Using a utility dimension to implement flexible display units

Measures are sometimes too precise for reporting needs. Either because they have decimals which distract us or because the numbers are very large, consisting of many digits, and therefore hard to memorize or compare with others. The phrase *can't see the forest for the trees* fits perfectly here.

Sometimes users like to see measures displayed in thousands or millions for ease of comparison. One way to accomplish that would be to divide those measures directly in the fact table by, let's say 1,000 or 1,000,000. We would of course have to specify the new unit in the title of the measure. However, that wouldn't be a good solution. In situations where we need the results to be as precise as possible, that would cause problems. As said, sometimes, but not always, there's a need to simplify the numbers.

The other way would be to generate a set of parallel calculated measures, one for each factor. That way we would have sales amount, then sales amount (000), and finally sales amount (000,000) or similar markings. Again, this is not a very good approach. End users would have a hard time finding the right measure in a set of so many calculated measures.

The next option is the best, although it can have its specifics that may demand our attention. It's the case of building a separate utility dimension to display values in thousands, millions, and so on. This way we can preserve the simplicity of the cube design while enjoying the benefits of being able to visualize measures in another metric.other metrics. This recipe shows how to achieve such a solution. It also tackles problems specific to this type of solution.

Getting ready

Open the SQL Server Data Tools (SSDT) and then open the Adventure Works DW 2016 solution. Once it loads, double-click on the **Adventure Works DW** data source view.

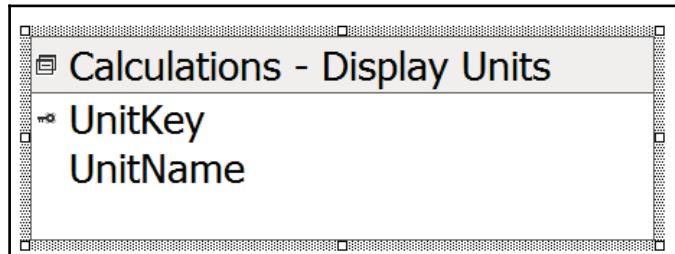

How to do it...

Follow these steps to create the utility dimension which displays results in various formats:

1. Create a new named query **Calculations – Display Units** with the following definition:

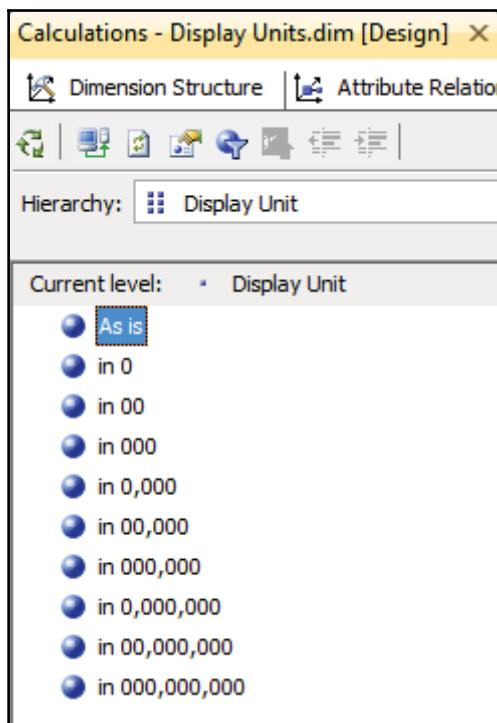

```
SELECT      0 AS UnitKey, 'As is' AS UnitName
UNION ALL
SELECT      1      , 'in 0'
UNION ALL
SELECT      2      , 'in 00'
UNION ALL
SELECT      3      , 'in 000'
UNION ALL
SELECT      4      , 'in 0,000'
UNION ALL
SELECT      5      , 'in 00,000'
UNION ALL
SELECT      6      , 'in 000,000'
UNION ALL
SELECT      7      , 'in 0,000,000'
UNION ALL
SELECT      8      , 'in 00,000,000'
UNION ALL
SELECT      9      , 'in 000,000,000'
```

2. Execute the query in order to test it. It should return 10 rows.
3. Set the `UnitKey` column as a `Logical Primary Key` column. The named query **Calculations – Display Units** should be like the following screenshot:

4. Create a new dimension using the previously defined named query and name it `Calculations – Display Units`.

5. Use the `UnitKey` column for the `KeyColumn` and the `UnitName` column for the `NameColumn` properties.
6. Name the attribute `Display Unit`.
7. Set the `IsAggregatable` property of the attribute to `False`.
8. Set the `OrderBy` property to `Key`.
9. Set the `ValueColumn` to `UnitKey` column.
10. Set the default member for the attribute to the `As is` member. The expression in the property should be `[Calculations - Display Units].[Display Unit].&[0]` once you're done.
11. Deploy and process in full the dimension. Then verify in the **Browser** tab of the **Dimension Editor** that your new utility dimension looks like the following:

12. Open the **Adventure Works** cube and add that dimension without linking it to any measure group.
13. Deploy changes by right-clicking on the project name (in the **Solution Explorer** pane) and choosing the **Deploy** action.

14. Go to the **Calculations** tab and add the following code to the beginning of the MDX script:

```
Create Hidden SET CurrentCube.[Display Units Set] AS
    Except( [Calculations - Display Units].[Display Unit].[Display
Unit],
            [Calculations - Display Units].[Display Unit].&[0] )
;
Scope( [Display Units Set] );
    This = [Calculations - Display Units].[Display Unit].&[0]
    /
    10 ^ [Calculations - Display Units].[Display Unit]
        .CurrentMember.MemberValue;
    Format_String( This ) = '#,##0';
End Scope;
```

15. Deploy the solution.
16. Go to the **Cube Browser** tab and build a pivot using the new dimension on the columns where you select only some members, for example, Display in thousands and **As is**. Put the **Gross Profit**, the **Sales Amount**, and the **Ratio to Parent Product** measures in the data area and the product categories on the rows. You should be able to see that the values are reduced as required for amounts, but not for the percentages:

	A	B	C	D	E	F	G
1		Display Unit					
2		As is			in 000		
3	Row Labels	Gross Profit	Sales Amount	Reseller Ratio to Parent Product		Reseller Ratio to Parent Product	
4	Accessories	\$634,467.16	\$1,272,057.89	0.71%	\$634.47	1,272	0.71%
5	Bikes	\$10,515,096.61	\$94,620,526.21	82.41%	\$10,515.10	94,621	82.41%
6	Clothing	\$368,836.00	\$2,117,613.45	2.21%	\$368.84	2,118	2.21%
7	Components	\$1,032,966.48	\$11,799,076.66	14.67%	\$1,032.97	11,799	14.67%
8	Grand Total	\$12,551,366.25	\$109,809,274.20	100.00%	\$12,551.37	109,809	100.00%

How it works...

The utility dimension, a dimension not related to any fact table of the cube, can be understood as a cube parameter. The logic we have implemented using the scope statement in the MDX script acts like a modification of the cube. The scope fires, if any members of that dimension are in context. The calculation specifies that the value of the measure will be reduced by factor 10 to the power of the member value of the current member. The formula can be so elegant because we used the `MemberValue` property, the same sequence of numbers as in the dimension key.

The definition of the scope says that the value of any measure will be divided by 10 to the power of N , where N is read from the `MemberValue` property of the current member of that utility dimension.

There's more...

Things don't run that smoothly. There are potential problems with this approach.

One is that we lose the format string of the measure (see the `Sales Amount` measure in the previous screenshot); the other is that the scope is applied to all the measures. Let's see what we can do about that.

Set-based approach

We can expand the scope and specify which measures we want in it. That way we can precisely control the format string for each set of measures.

Here's an example how it can be done. Add this new hidden set immediately after the previously defined hidden set and modify the scope as specified:

```
Create Hidden SET CurrentCube.[Measures Set] AS
    { [Measures].[Extended Amount],
        [Measures].[Freight Cost],
        [Measures].[Sales Amount],
        [Measures].[Standard Product Cost],
        [Measures].[Total Product Cost],
        [Measures].[Tax Amount] }
    ;

Scope( [Display Units Set],
    [Measures Set] );
This = [Calculations - Display Units].[Display Unit].&[0]
    /
    10 ^ [Calculations - Display Units].[Display Unit]
        .CurrentMember.MemberValue;
Format_String(This) = 'Currency';
End Scope;
```

Here's the same example using one regular, one calculated, and one ratio measure with the scope applied to the **in 000** member:

A	B	C	D	E	F	G
1	Display Unit ▾					
2	As is			in 000		
3	Row Labels	Gross Profit	Sales Amount	Reseller Ratio to Parent Product	Gross Profit	Sales Amount
4	Accessories	\$634,467.16	\$1,272,057.89	0.71%	\$634.47	\$1,272.06
5	Bikes	\$10,515,096.61	\$94,620,526.21	82.41%	\$10,515.10	\$94,620.53
6	Clothing	\$368,836.00	\$2,117,613.45	2.21%	\$368.84	\$2,117.61
7	Components	\$1,032,966.48	\$11,799,076.66	14.67%	\$1,032.97	\$11,799.08
8	Grand Total	\$12,551,366.25	\$109,809,274.20	100.00%	\$12,551.37	\$109,809.27
						100.00%

Only regular cube measures can be explicitly specified in the scope, not calculated ones. The effect will manifest in all subsequently defined calculated measures too because their definition is dependent on the values of regular measures and since the regular measures will be reduced, so shall the calculated measures.

The scoped set solution can be repeated many times. We can group measures of the same type in multiple sets and use an explicit format string for each of those sets. However, that's not too practical a solution. Moreover, the reduced values are still not readable. It would be great if we could lose decimals and currency symbols that distract us.

Format string on a filtered set approach

A more general way to specify various measures in the cube without having to list them all in the scope or hidden sets heavily depends on the naming convention used in the cube. We can filter all measures, regular and calculated ones, based on some criteria and apply the format only to those measures that don't have the words `Price`, `Margin`, `Ratio`, and so on in them. Here's an example for that.

Modify the definition of the `Measures Set` according to the following expression. Modify the scope statement, but move it to the end of the MDX script this time, not the beginning. Also, make sure the `Display Units Set` is still available in the MDX script since the scope is referring to it:

```
Create Hidden SET CurrentCube.[Measures Set] AS
  Filter( Measures.AllMembers,
    --MeasureGroupMeasures('Sales Summary'),
    InStr( Measures.CurrentMember.Name, 'Price' )
```

```
= 0 AND
InStr( Measures.CurrentMember.Name, 'Margin' )
= 0 AND
InStr( Measures.CurrentMember.Name, 'Percentage' )
= 0 AND
InStr( Measures.CurrentMember.Name, 'Growth' )
= 0 AND
InStr( Measures.CurrentMember.Name, 'Rate' )
= 0 AND
InStr( Measures.CurrentMember.Name, 'Ratio' )
= 0
)
;

Scope( [Display Units Set] );
Format_String( [Calculations - Display Units].[Display Unit].&[3]
              * [Measures Set] ) = '#,##0,';
Format_String( [Calculations - Display Units].[Display Unit].&[6]
              * [Measures Set] ) = '#,##0,,';
Format_String( [Calculations - Display Units].[Display Unit].&[9]
              * [Measures Set] ) = '#,##0,,,';
End Scope;
```

When deployed, this solution works just right. Open **Excel** and create a pivot; you can see that the amounts are formatted as numbers in 1,000s while the percentages remain as percentages:

	A	B	C	D	E	F	G
1		Display Unit ▾					
2		As is			in 000		
3	Row Labels ▾	Gross Profit	Sales Amount	Reseller Ratio to Parent Product	Gross Profit	Sales Amount	Reseller Ratio to Parent Product
4	Accessories	\$634,467.16	\$1,272,057.89	0.71%	634	1,272	0.71%
5	Bikes	\$10,515,096.61	\$94,620,526.21	82.41%	10,515	94,621	82.41%
6	Clothing	\$368,836.00	\$2,117,613.45	2.21%	369	2,118	2.21%
7	Components	\$1,032,966.48	\$11,799,076.66	14.67%	1,033	11,799	14.67%
8	Grand Total	\$12,551,366.25	\$109,809,274.20	100.00%	12,551	109,809	100.00%

The Gross Profit is a calculated measure, and is formatted as a currency in the MDX script. In order for the Format_String() function to work in the earlier scope statement, you need to remove the line Format_String = "Currency" from the Gross Profit calculation.

Notice that we didn't have to modify the actual values in the scope statement; we only changed the format string for certain measures. This makes it a faster approach.

The other thing to notice is that we were able to use both calculated and regular measures. That is because in the Format_String() function we are allowed to use both types of measures, whereas in the scope's definition we are not allowed to use calculated measures. By carefully constructing our expression, we were able to achieve the goal.

The only downside is that we only made it work for some members of the utility dimension, not all of them. However, that should not be a problem because those members are used most of the time anyway (in 000, in 000,000, in 000,000,000, and so on). In other words, if we stick with the latest solution, we can remove all not-used members from the utility dimension.

The commented part of the scope statement shows that we can limit the filter to one or more measure groups.

Using a utility dimension to implement time-based calculations

The MDX language implemented in SQL Server Analysis Services offers various time-related functions. Chapter 3, *Working with Time*, showed how they can be utilized to construct useful sets and calculations. The main focus there was to show how to make OLAP cubes time-aware; how to detect the member that represents today's date and then create related calculations.

In this chapter, we meet time functions again. This time our focus is to generate time-based calculations in the most effective way. One way to do it is to use the built-in **Time Intelligence Wizard**, but that path is known to be problematic. Best practice says we need a separate utility dimension instead, a utility dimension with members representing common time-based calculations like the year-to-date, year-over-year, previous period, and so on.

The idea behind the utility dimension is to minimize the number of calculations in the way that measures are combined with members of the utility dimension. That effectively means we have a Cartesian product of measures and their possible time-related variants. This is a more elegant approach than having many calculated measures in the cube, not to mention maintaining them or presenting them to end users.

Members of the utility dimension have more or less complex formulas. However, once we set them up in one project, we can use them in future ones. As long as we keep the metadata the same - the names of the attributes and levels of the date dimension and this utility dimension - the process comes down to copy/paste and is done in a minute. Does this sound tempting?

Getting ready

Open the SQL Server Data Tools (SSDT) and then open the Adventure Works DW 2016 solution. Once it loads, double-click on the **Adventure Works DW** data source view.

Before we start, I should inform you that this recipe is heavy on MDX. Although it has the longest code in the whole book, it is a very useful recipe. Once adjusted to your date dimension, the code can be reused in every project that has the same date dimension. If the dimension is the same as in the Adventure Works DW database, then no further modification is needed. I am by no means saying you should design your date dimension the way it is done in Adventure Works. You shouldn't. I'm merely saying you should start with that, read the explanations, analyze the code, and then adjust it to your needs.

How to do it...

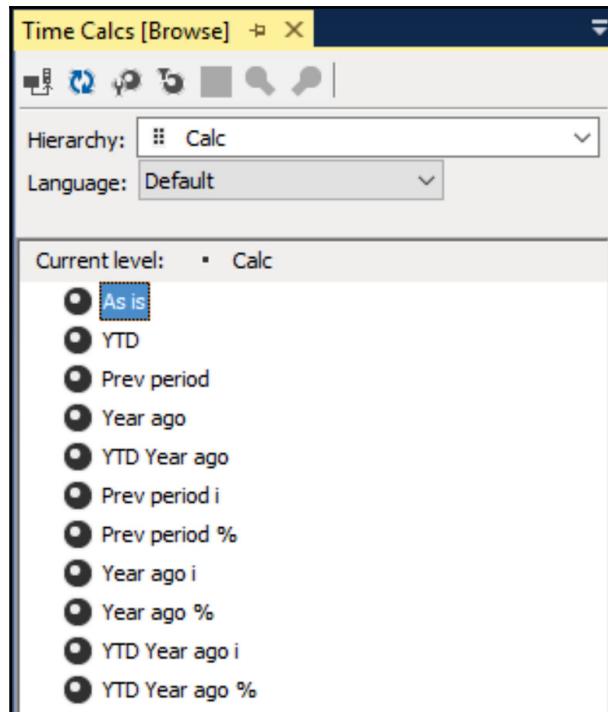

Follow these steps to create a utility dimension with relative time calculations:

1. Create a new named query `Time Calcs` using the following definition:

```
SELECT 0 AS ID, 'As is' AS Name
UNION ALL
SELECT 1      , 'YTD'
UNION ALL
SELECT 2      , 'Prev period'
UNION ALL
SELECT 3      , 'Year ago'
UNION ALL
SELECT 4      , 'YTD Year ago'
UNION ALL
SELECT 21     , 'Prev period i'
```

```
UNION ALL
SELECT 22      , 'Prev period %'
UNION ALL
SELECT 31      , 'Year ago i'
UNION ALL
SELECT 32      , 'Year ago %'
UNION ALL
SELECT 41      , 'YTD Year ago i'
UNION ALL
SELECT 42      , 'YTD Year ago %'
```

2. Execute the query in order to test it. It should return 11 rows. Then close the window.
3. Mark the **ID** column as the **Logical Primary Key** column.
4. Create a new dimension using the previously defined named query and name it **Time Calcs**.
5. Use the **ID** column for the **KeyColumn** and the **Name** column for the **NameColumn** properties.
6. Name the attribute **Calc**.
7. Once you finish with the wizard a **Dimension Editor** will show.
8. Set the **IsAggregatable** property of the attribute to **False**.
9. Set the **OrderBy** property to **Key**.
10. Set the **ValueColumn** to **ID** column.
11. Set the default member for the attribute to the **As is** member. The expression in that property should be **[Time Calcs].[Calc].&[0]** once you're done.
12. Deploy and process in full the dimension. Then verify the dimension in the **Browser** tab of the **Dimension Editor**.

13. Open the **Adventure Works** cube and add that dimension without linking it to any measure group, then deploy.
14. Now we're ready to write calculations. Go to the **Calculations** tab and position the cursor at the end of the MDX script.
15. Add the calculation for the YTD member. In the case of Adventure Works, the calculation should consist of three parts. The first two parts handle attribute hierarchies not related to the year level and thus enable them to be used in combination with the YTD member. The last part is a classic YTD calculation expanded to work for all visible attribute hierarchies that make sense to be used directly with the year level.

```
Scope( [Time Calcs].[Calc].[YTD] );
    -- focus on anything below and including year level
Scope( [Date].[Date].MEMBERS,
    [Date].[Calendar Year].[Calendar Year].MEMBERS );
    -- attribute hierarchies not related to year level
    -- and related to months
    -- i.e. day of month
Scope( [Date].[Month of Year].[Month of Year].MEMBERS );
    This = Aggregate(
```

```
YTD( [Date].[Calendar].CurrentMember ) *
YTD( [Date].[Calendar Weeks].CurrentMember ) *
{ null : [Date].[Month of Year].CurrentMember } *
{ null : [Date].[Day of Month].CurrentMember },
[Time Calcs].[Calc].&[0]
);

End Scope;
-- attribute hierarchies not related to year level
-- and related to weeks
-- i.e. day of week & day name
Scope( [Date].[Calendar Week of Year]
      .[Calendar Week of Year].MEMBERS );
This = Aggregate(
    YTD( [Date].[Calendar].CurrentMember ) *
    YTD( [Date].[Calendar Weeks].CurrentMember ) *
    { null : [Date].[Calendar Week of Year]
        .CurrentMember } *
    { null : [Date].[Day of Week].CurrentMember } *
    { null : [Date].[Day Name].CurrentMember },
    [Time Calcs].[Calc].&[0]
);
End Scope;
-- user hierarchies
-- and attribute hierarchies related to year level
This = Aggregate(
    YTD( [Date].[Calendar].CurrentMember ) *
    YTD( [Date].[Calendar Weeks].CurrentMember ) *
    { null : [Date].[Calendar Semester of Year]
        .CurrentMember } *
    { null : [Date].[Calendar Quarter of Year]
        .CurrentMember } *
    { null : [Date].[Month of Year].CurrentMember } *
    { null : [Date].[Calendar Week of Year]
        .CurrentMember } *
    { null : [Date].[Day of Year].CurrentMember } *
    { null : [Date].[Date].CurrentMember },
    [Time Calcs].[Calc].&[0]
);
End Scope;
-- performance is improved if we preserve empty cells
-- remove this to get continuous date ranges
This = iif( IsEmpty( [Time Calcs].[Calc].&[0] ),
            null,
            Measures.CurrentMember );
End Scope;
```

16. Notice the comments inside the calculation. They are there to help you understand what's going on.
17. Add the calculation for the `Prev period` member. The idea is to allow hierarchies to expand by one member to the left to include the previous period, apply the intersection, and then deduct the value in the current context from it. The result is the value in the previous period. The first part of the scope should handle user hierarchies; the second one is dedicated to attribute hierarchies. Please notice that our generic term *period* can be a month, a week or anything else depending on what we've put in the context. In order to expand to include the previous *period*, we have created a procedure to shift members in the circle. We will explain this procedure in detail later in the *There's more* section. When the intersection subcube contains only a single member, the circle shift procedure should produce the previous period. In case there is no previous year, an empty value should be returned.

```
Scope( [Time Calcs].[Calc].[Prev period] );
    -- user hierarchies, complete
    Scope( [Date].[Calendar].MEMBERS,
        [Date].[Calendar Weeks].MEMBERS );
        -- previous member exists? (null for "no")
        This = iif( Count( LastPeriods( 2, [Date].[Calendar]
            .CurrentMember ) *
            LastPeriods( 2, [Date].[Calendar Weeks]
            .CurrentMember ) )
            ) <= 1,
        null,
        -- include one member to the left on each
        -- hierarchy and see what comes out as the
        -- intersection, then deduct the value in
        -- the current context from it
        Aggregate(
            LastPeriods( 2, [Date].[Calendar]
                .CurrentMember ) *
            LastPeriods( 2, [Date].[Calendar Weeks]
                .CurrentMember ),
            [Time Calcs].[Calc].&[0]
            ) -
            [Time Calcs].[Calc].&[0]
        );
    End Scope;
    -- attribute hierarchies directly related to year level
    Scope( [Date].[Calendar Year].[Calendar Year].MEMBERS );
        -- previous member exists? (test prev year for "no")
        This = iif( Count(
            LastPeriods( 2, [Date].[Calendar Semester of Year]
```

```
        .CurrentMember ) *
LastPeriods( 2, [Date].[Calendar Quarter of Year]
        .CurrentMember ) *
LastPeriods( 2, [Date].[Month of Year]
        .CurrentMember ) *
LastPeriods( 2, [Date].[Calendar Week of Year]
        .CurrentMember ) *
LastPeriods( 2, [Date].[Day of Year]
        .CurrentMember ) *
LastPeriods( 2, [Date].[Date]
        .CurrentMember ) ) <= 1,
-- previous year exists? (null for "no")
iif( Count( LastPeriods( 2, [Date].[Calendar Year]
        .CurrentMember )

) <= 1,
null,
-- members shift in circle
-- from the first position to the last
-- hence we need the previous year
(
    [Date].[Calendar Year].PrevMember,
    [Date].[Calendar Semester of Year].LastSibling,
    [Date].[Calendar Quarter of Year].LastSibling,
    [Date].[Month of Year].LastSibling,
    [Date].[Calendar Week of Year].LastSibling,
    [Date].[Day of Year].LastSibling,
    [Date].[Date].LastSibling,
    [Time Calcs].[Calc].&[0]
)
),
-- include one member to the left on each
-- hierarchy and see what comes out as the
-- intersection, then deduct the value in the
-- current context from it
Aggregate(
    LastPeriods( 2, [Date].[Calendar Semester of Year]
        .CurrentMember ) *
    LastPeriods( 2, [Date].[Calendar Quarter of Year]
        .CurrentMember ) *
    LastPeriods( 2, [Date].[Month of Year]
        .CurrentMember ) *
    LastPeriods( 2, [Date].[Calendar Week of Year]
        .CurrentMember ) *
    LastPeriods( 2, [Date].[Day of Year]
        .CurrentMember ) *
    LastPeriods( 2, [Date].[Date].CurrentMember ),
    [Time Calcs].[Calc].&[0]
) -
```

```
        [Time Calcs].[Calc].&[0]
    );
End Scope;
End Scope;
```

18. The next calculation is relatively simple compared to those before. Define the calculation for the Year ago member, a member that returns the value for the same period in the previous year:

```
Scope( [Time Calcs].[Calc].[Year ago] );
    -- focus on anything below and including year level
    Scope( [Date].[Date].MEMBERS,
        [Date].[Calendar Year].[Calendar Year].MEMBERS );
        -- jump one year back on both user hierarchies
        This = ( ParallelPeriod( [Date].[Calendar].[Calendar Year],
            1,
            [Date].[Calendar].CurrentMember ),
            ParallelPeriod( [Date].[Calendar Weeks]
                .[Calendar Year],
            1,
            [Date].[Calendar Weeks]
                .CurrentMember ),
            [Time Calcs].[Calc].&[0]
        );
    End Scope;
End Scope;
```

19. Adding the YTD variant of the previous calculation is also easy. To define the YTD Year ago member, simply use the YTD member of the utility dimension in the definition used for the Year ago member:

```
Scope( [Time Calcs].[Calc].[YTD Year ago] );
    -- focus on anything below and including year level
    Scope( [Date].[Date].MEMBERS,
        [Date].[Calendar Year].[Calendar Year].MEMBERS );
        This = ( ParallelPeriod( [Date].[Calendar].[Calendar Year],
            1,
            [Date].[Calendar].CurrentMember ),
            ParallelPeriod( [Date].[Calendar Weeks]
                .[Calendar Year],
            1,
            [Date].[Calendar Weeks]
                .CurrentMember ),
            -- don't forget to use the YTD member this time
            [Time Calcs].[Calc].[YTD]
        );
    End Scope;
```

20. Now that we've defined the main calculations, we're ready to proceed with indexes and percentages. The first indicator (`Prev period i`) determines the difference from a previous period, the second one (`Year ago i`) from a year ago and finally, the third one (`YTD Year ago i`) also from a year ago, but cumulatively (`YTD`). All of them are additionally formatted with a red font color for negative values. The `i` stands for index.

```
Scope( [Time Calcs].[Calc].[Prev period i] );
    This = [Time Calcs].[Calc].&[0] -
        [Time Calcs].[Calc].[Prev period];
    Fore_Color(This) = Abs( Measures.CurrentMember < 0 ) * 255;
End Scope;

Scope( [Time Calcs].[Calc].[Year ago i] );
    This = [Time Calcs].[Calc].&[0] -
        [Time Calcs].[Calc].[Year ago];
    Fore_Color(This) = Abs( Measures.CurrentMember < 0 ) * 255;
End Scope;

Scope( [Time Calcs].[Calc].[YTD Year ago i] );
    This = [Time Calcs].[Calc].[YTD] -
        [Time Calcs].[Calc].[YTD Year ago];
    Fore_Color(This) = Abs( Measures.CurrentMember < 0 ) * 255;
End Scope;
```

21. Add the code for three indicators in the form of percentages: `Prev period %`, `Year ago %` and `YTD Year ago %`. The `%` sign stands for the value expressed in the form of a percentage:

```
Scope( [Time Calcs].[Calc].[Prev period %] );
    This = iif( [Time Calcs].[Calc].[Prev period] = 0, null,
        [Time Calcs].[Calc].&[0] /
        [Time Calcs].[Calc].[Prev period] - 1);
    Format_String(This) = 'Percent';
    Fore_Color(This) = Abs( Measures.CurrentMember < 0 ) * 255;
End Scope;

Scope( [Time Calcs].[Calc].[Year ago %] );
    This = iif( [Time Calcs].[Calc].[Year ago] = 0, null,
        [Time Calcs].[Calc].&[0] /
        [Time Calcs].[Calc].[Year ago] - 1);
    Format_String(This) = 'Percent';
    Fore_Color(This) = Abs( Measures.CurrentMember < 0 ) * 255;
End Scope;

Scope( [Time Calcs].[Calc].[YTD Year ago %] );
```

```

This = iif( [Time Calcs].[Calc].[YTD Year ago] = 0, null,
            [Time Calcs].[Calc].[YTD] /
            [Time Calcs].[Calc].[YTD Year ago] - 1);
Format_String(This) = 'Percent';
Fore_Color(This) = Abs( Measures.CurrentMember < 0 ) * 255;
End Scope;

```

You're done with calculations! Now, deploy changes in the MDX script and test the solution in Excel by clicking on the **Analyze in Excel** icon in the **Cube Browser** tab.

22. Calculations should work correctly no matter which hierarchy you take in the pivot, as long as you don't use fiscal hierarchies. See the following screenshot with two attribute hierarchies on the rows, years and months:

	Sales Amount	Calc											
1	Sales Amount	Calc											
2	Calendar	Year/Month	As is	YTD	Prev period	Year ago	YTD Year ago	Prev period i	Prev period %	Year ago i	Year ago %	YTD Year ago i	YTD Year ago %

How it works...

The solution presented in this recipe is a long one. Therefore we'll break the explanation into several phases.

The first phase was creating the utility dimension. We created the utility dimension in DSV. It can also be created in DW.

The process of creating a utility dimension is pretty straightforward. The first member becomes the default member, the All member is disabled. Other actions help but are not mandatory. I do suggest you make them though.

The second phase started when we defined four main calculations and assigned them to members of the utility dimension. We used one or more scope statements for that, to precisely determine the context in which particular assignments should be applied.

The first of these calculations defined what should happen when the YTD member gets selected in the utility dimension. To remind you, this was done in step 16.

The outer scope in that calculation limits the cube space to anything including and below the year level which is exactly the subcube that YTD calculation should be applied to.

The first thing we did is provide the assignments for two attribute hierarchies—the Month of Year and the Calendar Week of Year hierarchy. This is not a mandatory step when defining YTD calculations and you'll rarely see it made. However, it pays off to implement it because those additional assignments enable the usage of all attribute hierarchies for the YTD calculation. In other words, they allow us to combine several attribute hierarchies as if they were levels of a natural user hierarchy.

Additional assignments like these come with a prerequisite—our guarantee that they make sense in the particular context. This is defined using the scope subcube.

If you take one more look at the YTD calculation, you'll notice that YTD values for the Day of Month hierarchy will only be calculated when months are also present in the context. Similarly, it makes sense to calculate the YTD values for Day of Week and Day Name hierarchies too, but only when weeks are in the context. This is how the invisible time sequence gets established.

The third assignment in that calculation is the one made for the user hierarchies and all attribute hierarchies that make sense to be used together with years. Just like in the previous assignments, two natural user hierarchies are used to collect the YTD range while all other hierarchies filter that context by interacting with it in the form of intersections. What comes out of that intersection is a subcube that represents the YTD values for that particular context.

The Prev period member is also a complex one. Again, we have two scopes: one for user hierarchies and the other for attribute hierarchies. In order to keep things concise, we'll explain the logic behind this calculation by focusing on the main intentions here.

The idea behind calculating the value in the previous period is to extend every current member with its previous member, aggregate that, and deduct the value in the current context from that. What comes as the result is the value in the previous period.

Notice how we keep using the generic term *period*. It's not a month, it's not a week; it can be anything depending on what we've put in the context. The shape of the subcube is not our concern. All we have to do is provide a potential subcube for this calculation. In the case of the `Prev period` member, we did that by specifying the current and previous member for each relevant hierarchy. So, the idea of chasing the current or existing members of every hierarchy, and then detecting whether they've moved or not is not the way to go. We should think in terms of sets and allow the engine to do the magic by intersecting members in the provided subcube.

Two additional things were important in the previous period calculation. First, counting is a way of detecting when we're on the first member of a hierarchy when multiple hierarchies are involved. When we encounter the first member, we either have to shift the year by minus one (by referring to the previous member), or to provide `null` because there's nowhere to go. Second, when we shift the year to the previous one, we also need to move other attribute hierarchies to their last member. At first, this may seem strange, but it's actually not. It's something we do unconsciously every day. Here's an example, proving that.

The year that precedes the year 2000 is the year 1999. In order to evaluate that, we do the following procedure. We slice the year by its digits and analyze them. We then realize that all the digits on the right are the first digits in the list of digits, 0 being the first digit in the decade system and 9 being the last. Because of that, we change the 2 into its preceding digit, the digit 1. At the same time, we shift all other digits by one place, as if 0 and 9 were connected in a circle. In other words, all other digits jump from the first digit, 0, to the last one, the 9. The same principle was applied here, the year hierarchy being the leftmost digit 2 and the other hierarchies being digits 0 on the right.

But what will happen in that calculation? Again, we're letting the current members decide what the result of the intersection will be. If any of them is on the root member, that member will not influence the intersection. That's a single member on its level which means the `LastSibling()` function, used to shift members in a circle, will return the same member. When another member is active, we'll jump to the last member of that level, for example to Q4, December, and so on. Again, the most selective members of all hierarchies determine the final subcube.

In the third calculation, the `Year ago` member is calculated using two user hierarchies. The tuple is formed using two `ParallelPeriod()` functions that return the member in the previous year. Naturally, the last part of the tuple is the default member of the utility dimension.

As this was a relatively easy calculation, let's explain what the default member of the utility calculation does in expressions.

The cube is a multidimensional structure which means every time we make a reference to a particular subcube, the coordinate of that subcube is also multidimensional. Fortunately, we don't have to specify all of the hundreds or more hierarchies a typical cube has; the server does that for us by implicitly including all unmentioned hierarchies in every tuple we make. The term tuple is just another word for the coordinate in the cube space.

Implicit hierarchies are included using their current members at the time of the evaluation of the tuple.

In the case of the calculations presented in this recipe, now it becomes clear that the current measure is already there implicitly in every expression. There's no reason to be explicit about that.

What's not obvious at first is that the hierarchy of the member we're defining is also inside the tuple. Yes, the utility dimension. Now, guess what will be its current member at the time of that evaluation? The same `Year ago` member we're defining. That's the current member in that moment! That would lead to an empty result as the value of the calculated members is `null` in advance. We must replace it and the only way to do that is to be explicit and specify another member of that dimension inside the tuple. The member that should be there is the default member of the utility dimension. That's our `As is` member, a single member of that dimension which doesn't modify the result of the current measure. Remember, the dimension is in no way related to the cube and that member is the only one without a calculation on it. Therefore, it preserves the results of the cube and keeps it unmodified, so that it can be used as such in other calculations.

By placing the default member of the utility dimension inside the tuple (actually, in all calculations so far), we're basically saying, *calculate this expression using the unmodified current measure, whatever it may be*. In the beginning, it may seem a bit strange, but once you understand the concept of the unrelated utility dimension, it's easy to read expressions, because this is a standard way of writing calculations for members of the utility dimension.

We're progressing. Let's see what comes next.

The YTD Year ago member has the same definition like the Year ago member except for a small detail – instead of the default As is member, the YTD member was used in the calculation. How come?

A moment ago we explained the purpose of the As is member and its behavior in calculations. We said that it's there to force the unchanged measure. This time, however, we'd like to be smart and apply the YTD calculation not on the value of the current member, but on the value of the member in the previous year which is exactly what the Year ago member calculates. It jumps to the previous year and grabs the corresponding value.

Wouldn't it be nice to combine the YTD and the Year ago calculations? Definitely, and it's not that difficult. All we have to do is make the composition of calculations. The result of the inner calculation (the value of the Year ago member) is passed as an argument to the outer one, the YTD calculation. That's one of the benefits of implementing the utility dimension.

Slowly, we come to the last phase. In this part, six more calculations are created. The first three calculate the difference between previously defined members of the utility dimension. The other three express that difference in the form of a percentage. All six calculations are relatively simple and easy to comprehend just by taking a look at them. This is because, again, the calculations refer to other members of the utility dimension. In other words, the calculations for some of the members in the utility dimension are rather complex; however, all subsequent calculations become relatively simple and easy.

Finally, a word or two about highlighting the negative results. When the value of True gets converted to a number, it becomes -1. The numeric value of False is 0. The Abs () function was used to correct the negative sign.

There's more...

This section contains additional information regarding the concept presented in this recipe.

Interesting details

It's worth mentioning that both user hierarchies have the year level clearly marked as the Year type. This way we had no problem using the YTD () function. If it weren't the case, the alternative would be to use the PeriodsToDate () function and to manually specify the year level in it.

Next, the Adventure Works cube has a date dimension that starts with July. Therefore, the values of the Year ago calculations appear shifted by a half year. Fortunately, that happens only in the second year and only when user hierarchies are used. I believe your date dimension follows the best practice and has the complete year starting from January and ending with December. In that case, you won't experience any problems with these calculations.

Another interesting thing is that neither of the calculations uses any measures in the assignments. That's a feature of the utility dimension and how we make assignments using it. Any time we need to reference the current measure, we reference the default member of the utility dimension instead. When applicable, we can also refer to other members of that dimension, for example, the way we defined the calculation for the YTD Year ago member.

You may be wondering why none of the fiscal hierarchies were included in the calculation. That's because they are not compatible with calendar hierarchies. They break years into two. The proper way to include them would be to define a separate YTD member on the same utility dimension or to make another utility dimension just for fiscal hierarchies. Naturally, that would allow us to use the same time calculations only modified to fit the fiscal hierarchies.

Here's another interesting detail about the YTD calculation. We don't have to know, imagine, or visualize the result of the intersection that happens inside the `Aggregate()` function (although it's possible). All that matters is that we provide a way for this intersection to happen and we did that by specifying all attribute hierarchies there. The trick with that expression is to form ranges that span from the first member of a particular hierarchy (represented using `null` in the code) up to the current member of each attribute hierarchy. That way each attribute hierarchy has the potential to determine the subcube, but on the other hand, every other hierarchy is slicing that subcube with its range of members. The result is the smallest common subcube, the one which fits all hierarchies in the `Aggregate()` function.

This concept repeats, with few modifications, in other calculations.

Fine-tuning the calculations

It is possible to add a couple of scope statements to hide values on future dates, as explained in the recipe *Hiding calculations values on future dates* in Chapter 3, *Working with Time*. For example, this is how one of those scope statements would look:

```
Scope( { Tail( NonEmpty( [Date].[Date].[Date].MEMBERS,  
[Measures].[Transaction Count] ),
```

```
    1 ).Item(0).NextMember : null } );
This = null;
End Scope;
```

The other things we can do to improve the solution is to provide a scope that forces the default member of the utility dimension in case a multi-select is made in the slicer. Here's the code for that:

```
Scope( [Time Calcs].[Calc].MEMBERS );
This = iif( Count( EXISTING [Time Calcs].[Calc].MEMBERS ) > 1,
            [Time Calcs].[Calc].&[0],
            [Time Calcs].[Calc].CurrentMember );
End Scope;
```

Other approaches

The following link presents another implementation of the time-based utility dimension, the `DateTool` dimension created by *Marco Russo*: <http://tinyurl.com/MarcoDateTool>.

Where these approaches differ from each other is that the one presented in this book supports multiple hierarchies and doesn't use string operations. Because of that, its code grew much bigger and became more complex. Actually, the code for both approaches looks difficult to understand, if you're not used to these types of MDX expressions, with lots of scopes and assignments in them. However, that shouldn't stop you from experimenting and applying them in your solutions.

The approaches also differ in the use of single or multiple hierarchies of the utility dimension. This is just a matter of taste; both techniques can be switched to the other style, with a little bit of coding of course.

- The recipes *Calculating the YTD (Year-To-Date) value* and *Calculating the YoY (Year-over-Year) growth (parallel periods)*, both in Chapter 3, *Working with Time*, show the additional information about YTD and year ago calculations. Actually, the complete chapter may be useful because the majority of the topics in that chapter are time calculations.

9

Metadata - Driven Calculations

In this chapter, we will cover the following recipes:

- Setting up the environment
- Creating a reporting dimension
- Implementing custom rollups using MDX formulas
- Implementing format string, multiplication factor, and sort order features
- Implementing unary operators
- Referencing reporting dimension's members in MDX formulas
- Implementing the MDX dictionary
- Implementing metadata-driven KPIs

Introduction

Metadata-driven approaches have been studied, found useful, and applied in many fields, such as the IT industry, manufacturing, and so on. The main idea is to avoid hard-coding or use it as little as possible. Less hard-coding means that the system we are designing becomes more complex and more difficult to create. So, what are the benefits? Why should we do it in the first place? We should do it because later there's less maintenance for those who create such systems and more flexibility for users. Is that a good enough reason to start moving in that direction? Definitely!

Here's one example to illustrate this principle better.

Not so long ago mobile phones had small screens and numerous buttons (keypad). The buttons were preprogrammed for what they could do. Numbers 0-9 were used to type a phone number, the green button to make the call, and the red button to hang up or cancel an operation. In addition to that, those old phones had two to three extra buttons, **empty** buttons, under the screen. They did various things, that is, they could be used to go **up/down** in the menu, open the calculator, turn on the camera, and so on. Interestingly, they could be reprogrammed in terms of what they do on the home screen. Reprogrammed by us, the end users! Other than that, everything was static.

The hardware engineer designed the old phones with many *hard-coded* buttons and 2-3 *empty* ones, not knowing in advance how many actions the phone will support. The result of that is that the phone's usage became more complex-a menu navigation system was required because those extra buttons were not used to simply start an action; they were used to find an action among the many actions in the phone's menu and then start it.

The fact that not every button had a *hard-coded* functionality was a great flexibility for the software engineer. The software engineer could program many actions, as many as it was required, all on the same hardware because the hardware was *open* in that respect. However, in some respects it was static, predefined. A step forward in providing flexibility for those who came next in the chain, phone users, was the moment the software engineer decided to allow us to define what the extra buttons would do (by storing this information somewhere in the phone and loading it each time the phone started).

Today, our phones are touch-based, with big screens, and few buttons. We use gestures to interact not only with the buttons that appear on the screen, but also with slide bars, zoom in on areas, such as pictures and maps, and so on. Only a few things remained *hard-coded*: the standby button, the volume up/down button, and buttons at the bottom of the phone. The rest was drawn on the screen, which means that the options were unlimited. Again, we can configure what appears on our home screen, which icons/tiles are there, what they display, what's their size, skin, action behind, and so on. This configuration is again stored somewhere on the phone and loaded every time we turn on the phone. Probably also backed up somewhere in the cloud and loaded when we switch from one device to another.

Mobile phones are metadata-driven. A part of their functionality and appearance is in the users' hands, especially in modern phones. Users can tweak them and this information is saved, and they can change things any time they want to, any time they need to. There's no need for support. Everything is in the users' hands and they like that flexibility!

Could we achieve the same effect in SSAS solutions? Is it possible? What would it look like?

Yes, we can!

SSAS developers can create cube calculations and KPIs using MDX expressions. Those calculations and KPIs are analyzed by business users. Every time a business user needs a new KPI or to change an existing calculation, SSAS developer must be engaged. This chapter shows how to design a flexible solution where end users can define calculations using a special reporting dimension. This dimension should be maintained in the MDM system (Master Data Management system, see <http://tinyurl.com/wiki-MDM> and <http://tinyurl.com/why-MDM> for more info); however, to keep things simple we will use Excel and a linked server to load the data into SQL Server.

Once we have the environment ready and the Excel file is filled with reporting items, we will take a step-by-step approach to add this dimension to the cube, set up unary operators and custom rollups, implement various properties, such as format string, multiplication factor, and apply a scope statement to fine-tune the result.

There's also a recipe that shows how to make the solution more user-friendly.

The last recipe in this chapter shows how to create a metadata-driven KPI solution system.

Setting up the environment

As explained in the introduction, the proper way of implementing metadata-driven calculations in the cube would be to store the metadata information in the MDM system. For explaining the concept, we will simplify things and use a common Excel file, which should be available to everyone. The data in that Excel file needs to be loaded into SQL Server first, it can't go straight to the cube. Therefore, we need to set up the environment that enables the data manipulation and loading process.

Getting ready

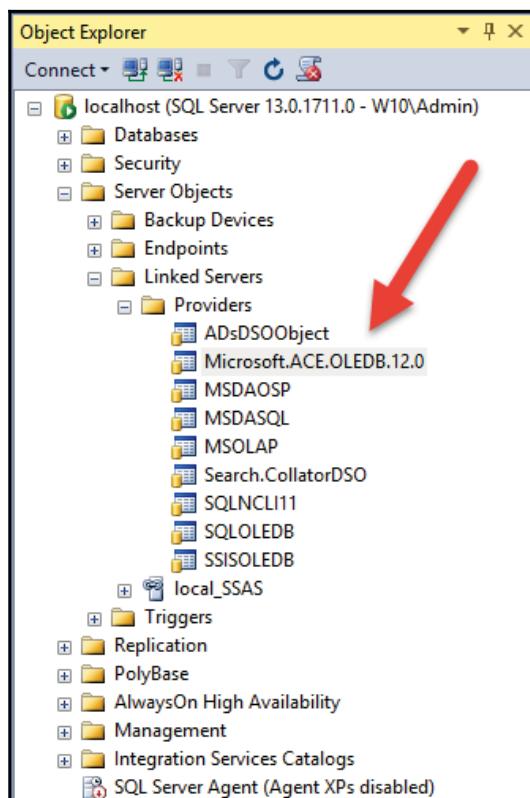

Data manipulation will be done in Excel, so make sure you have it installed on your dev machine, where you're learning and testing all this and make sure it is a 64-bit version or you might have problems with the driver later. SQL Server, Excel, and the driver must be of the same version, 64-bit.

For the data loading process, we will set up a linked server connection to the Excel file using a special free driver, which needs to be downloaded and installed first. Once we have the driver installed we will set up a view as a layer between the linked server and our SSAS project.

How to do it...

Follow these steps to set up the environment for the subsequent recipes in this chapter:

1. Open your web browser and navigate to the following site: <http://tinyurl.com/MADE2010R>.
2. Once there, select your language and click on the **Download** button. Download the 64-bit version because SQL Server 2016 is a 64-bit software.
3. When the file is downloaded, double-click on it to start the installation process. The process is straightforward, simply follow the procedure.
4. When the installation is done, start the SQL Server Management Studio and connect to your database instance, then expand the **Server Objects** category, **Linked Servers**, and **Providers**. A new provider named **Microsoft.ACE.OLEDB.12.0** should be listed under the **Providers** folder, as shown in the following screenshot:

5. Click on the **New Query** button, then execute the following statements:

```
EXEC sp_MSset_oledb_prop N'Microsoft.ACE.OLEDB.12.0',
    N'AllowInProcess', 1
GO
EXEC sp_MSset_oledb_prop N'Microsoft.ACE.OLEDB.12.0',
    N'DynamicParameters', 1
GO
```

6. Verify that no errors have occurred.
7. Next, open Windows Explorer, navigate to your Cdisk, and create the **Test** folder there. Here's where we will keep our Excel file with metadata. Of course, you are free to choose another folder if you like, just make sure you adjust all the folder references in subsequent steps to the folder of your choice.
8. Start **Excel**, select the **Blank Workbook** template, and save this file in the **C:\Temp** folder (or the folder of your choice). Name it **Metadata.xlsx**. Don't close the Excel sheet yet.
9. Rename the active tab as **Report_Items**.
10. Type the following table headers in row 1 (or copy-paste these items transposed into Excel by copying from here, pasting in cell **A2**, cutting the selection, and pasting the transposed items in cell **A1**):

ID
Name
Description
Sort_Order
Parent_ID
Reporting_Category
Level_of_Importance
Unary_Operator
Multiplication_Factor
Unit_of_Measure
Format_String
Calculation_Type

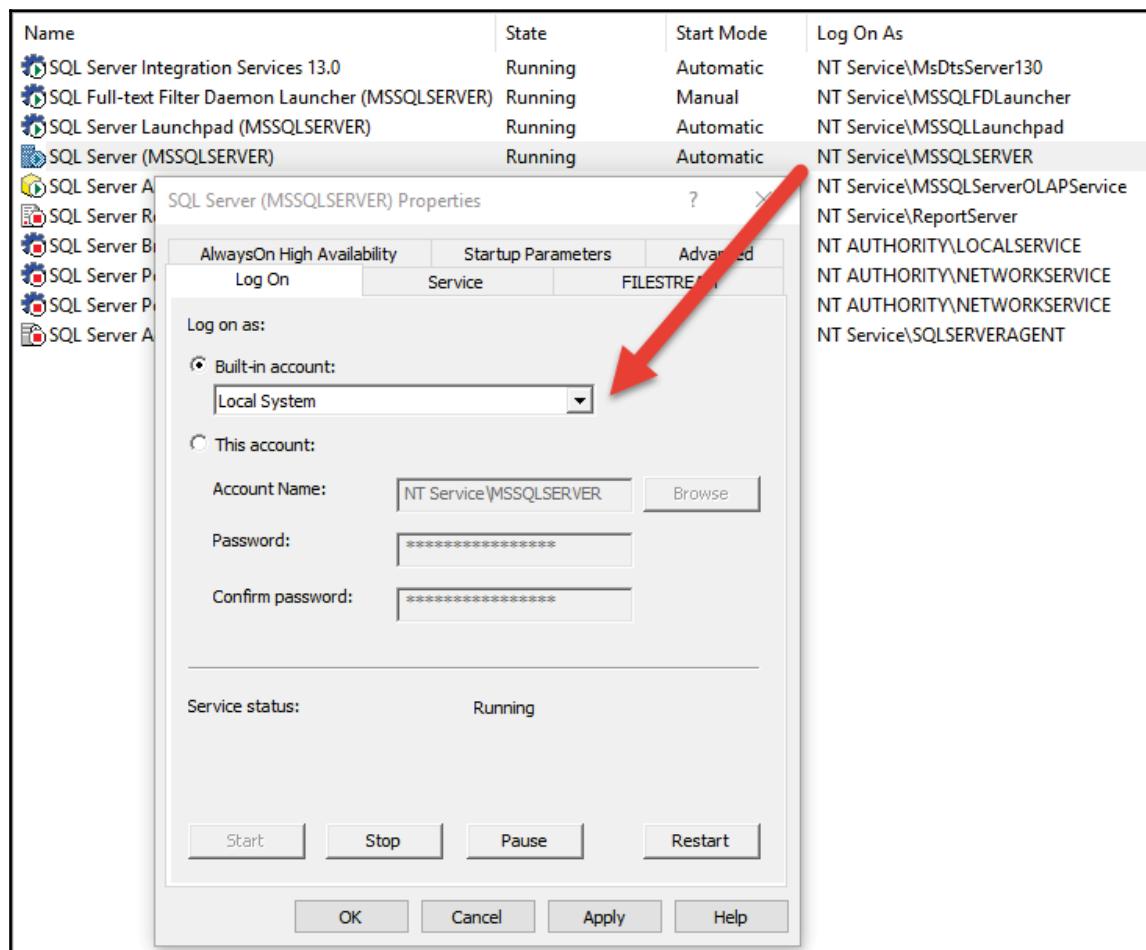

Formula_Flag
Formula_MDX
Formula_User_Friendly
Formula_Description
Is_Growth_Positive
Target
Status_Low
Status_High
Detailed_Report_URL

11. Format this table using the **My table has headers** option.
12. Specify the **Number** format for these columns: **Sort_Order**, **Level_of_Importance**, **Multiplication_Factor**, **Formula_Flag**, **Threshold_Low**, and **Threshold_High**. Then specify the **Text** format for the rest of the columns not mentioned in this step.
13. Save the workbook and close it.
14. Return to the SQL Server Management Studio and configure a new linked server targeting our Excel file by executing the following statement:

```
EXEC sp_addlinkedserver
    @server = 'MetadataExcel',
    @srvproduct = 'Excel',
    @provider = 'Microsoft.ACE.OLEDB.12.0',
    @datasrc = 'C:\Test\Metadata.xlsx',
    @provstr = 'Excel 12.0;IMEX=1;HDR=YES;'
```

15. Click the **Start** button and open the **SQL Server Configuration Manager**. If you can't find it on your computer, the following link might help:
<http://tinyurl.com/find-SSCM>.

16. Locate your SQL Server database instance. If the instance is being run by an NT Service\MSSQLSERVER account, you might experience problems using linked servers. Change it to a built-in **Local System** account for the purpose of this exercise.

17. Restart the service. After a while, verify that the service instance is now running under the **Local System** account.

18. Test your newly created linked server by refreshing the **Linked Servers** folder in the **Management Studio** and expand the new **Metadata Excel** server until you reach the **Report_Items\$** table. If you manage to do this, your linked server is configured properly. If you get an error, try to find out what went wrong in the preceding steps or see the *Additional information* section for troubleshooting.
19. Create a select statement and execute it:

```
SELECT * FROM OPENQUERY(MetadataExcel,
    'SELECT * FROM [Report_Items$]')
```

20. Feel free to replace the * in the inner select with the column names. Creating a script from the table in the expanded linked `MetadataExcel` server will help you get the list of columns. This is done by right-clicking on the table name (`Report_Items$`) and then selecting **Script Table as, SELECT To, and New Query Editor Window**.
21. Turn this into a view named `[dbo].[vReportItems]` and save it in the Adventure Works DW 2016 database by executing it. Verify that the view is there and that it returns results without any errors.
22. Finally, use Management Studio to execute the following script, which corrects the dates in the Adventure Works DW 2016 database:

```
use [AdventureWorksDW2016]
go

update [dbo].[DimDate]
set [FiscalQuarter] =
    case when [CalendarQuarter] < 3
        then [CalendarQuarter] + 2
        else [CalendarQuarter] - 2
    end,
    [FiscalYear] =
    case when [CalendarSemester] = 2
        then [CalendarYear] + 1
        else [CalendarYear]
    end,
    [FiscalSemester] =
    case when [CalendarSemester] = 2
        then 1
        else 2
    end
go
```

How it works...

Creating a linked server targeting Excel file is one of the methods of loading the data from Excel files into SQL Server. The other is using SSIS (Integration Services). Although it has its advantages (see the *There's more...* section if you failed with creating the linked server by applying the previous steps), it would unnecessarily complicate things in this recipe. Therefore, we use the linked server option.

The linked server option requires that we install the 64-bit driver for Excel, so we did that in the first part of this recipe.

The next part dealt with setting up the parameters for the provider, so that it can function properly. The other way of doing this is to double-click on the provider and enable those options using checkboxes.

Once we had the provider configured, we created an Excel file with empty tables but with headers so that we can have a structure that the query will return.

Then we created a new linked server targeting the Excel file. In this process, we used certain parameters in order to avoid common errors while reading data from Excel. What these parameters do can be read in the *Tips and Tricks* section.

We also changed the account that is used to run the database engine instance of your SQL Server 2016 to avoid problems with the default account. After the change we were ready to write and execute the query, that is, to test the connection to the Excel file.

The query was written using the `OpenQuery()` method because that allows more flexibility than simply referring to the linked server and its objects (tables in this case).

The query is then stored in our database as a view, so that we can use it in the subsequent chapters to load the data into a new dimension.

The last step was to avoid strange results in the following recipes. The problem is that the Adventure Works DW 2016 database has bad financial dates in calendar year 2011, so this was fixed using that update script.

There's more...

As stated in the previous section, the other method of getting the data from Excel into SSAS is to load it via a SSIS package. The difference is the following:

- The SSIS method loads the data into a table and therefore the package should be executed every time we need to load the data
- A view targeting the linked server is merely a layer on top of Excel; no data is stored in SQL Server and hence this option is better for testing and development when there's lot of modifications
- The SSIS method works in mixed environments, that is, when the Excel is 32-bit and SQL Server is 64-bit; the linked server doesn't because the driver had to match
- Both the SSIS and linked server will error when they try to read the Excel file in the moment when it is opened by a user; however, since SSIS loads the data into a table in SQL Server, processing or any data load in SSAS will not trigger an error because in case of SSIS the data is loaded from a table and only briefly refreshed from Excel into a table when the package is executed; the linked server is more prone to errors because it reads the data every time it's referred to
- In the SSIS package, we can provide additional logic for testing the existence of the Excel file and its availability, making it a more bulletproof solution than a linked server on, and hence more suitable for a production environment

There might be even more differences, but these are enough to understand why we chose the linked server option for this chapter and why you should consider the SSIS package version for production.

The same is with the MDM system. This chapter is based on an Excel file, while in production you should consider an MDM-based solution. In case of an MDM, the linked server versus SSIS dilemma drops or, to put it differently, moves to another level. Again, we would use a view. Now, this view could either directly target the MDM database or another database where the data is transferred using SSIS:

- Directly targeting MDM means that we can refresh the SSAS dimensions instantly. Transferring data means we will have a delay, we must create the SSIS package and schedule its execution.
- Opposite to Excel, here we don't have the locking issue of someone working on metadata in MDM.
- There's also no issue with 32-bit versus 64-bit environments.
- Either the SSAS service account or SSIS service account should have read access to MDM; again, not much difference for both scenarios.

So, based on this, it looks like it's better to avoid SSIS in case of MDM because that allows a faster refresh of SSAS dimensions based on MDM data and you can also see why it's better to go via MDM instead of Excel files.

Additional information

The focus of this recipe was on how to set up the environment. That process involved shifting through several applications (web browser, Windows Explorer, Management Studio, Configuration Manager, Excel, and so on). That's why we didn't go much into detail of how linked servers behave; if you want to find out more or troubleshoot your configuration, read the *Executing MDX queries in T-SQL environments* recipe in Chapter 10, *On the Edge*.

Another place where you can get a good overview of how to load data from Excel in SQL Server is: <http://tinyurl.com/excel-sql>.

Tips and tricks

In the script for creating a linked server, for an Excel file, we used two parameters. Here's what they are for:

- IMEX=1: This means that columns can have mixed data types (otherwise Excel makes its own estimate of the data type based on the first couple of rows with data, which you should generally avoid)
- HDR=YES: This means that column headers exist (they become column names)

Don't forget to use them when you set up your linked servers targeting Excel files.

See also

- The related recipe is *Executing MDX queries in T-SQL environments* in Chapter 10, *On the Edge*

Creating a reporting dimension

Now that everything is set up, we can enter the metadata in the Excel file, create a dimension in the SSAS database, and add it to the cube.

Getting ready

Open the `Metadata.xlsx` file that you saved in the previous recipe. It's time to put some data in it.

Add the following data in the corresponding columns:

ID	Name	Description	Parent_ID
S	Sales Indicators	Placeholder	
S01	# of Customers		S
S05	# of Orders	Internet Orders + Reseller Orders	S
S06	# of Internet Orders		S05
S07	# of Reseller Orders		S05
S12	Reseller Sales (in 000)		S
S16	Internet Sales (in 000)		S
S18	Product Sales (in 000)		S
I	Internal Indicators	Placeholder	
I01	Headcount	Number of employees	I
I02	Square Footage (in 000)		I

Save the file and close it. Then start SQL Server Management Studio and connect to your SQL Server 2016 database engine instance. Click on the **New Query** button, set the database to Adventure Works DW 2016, and check that the view you created in the previous recipe works by executing the following statement:

```
SELECT * FROM [dbo].[vReportItems]
```

If the query returned 11 rows, you're ready to create the reporting dimension. If there was an error, make sure that the Excel file is closed, is in the right place, and your linked server is working. See the previous recipe for more info.

How to do it...

Follow these steps to create a reporting dimension and add it to the Adventure Works cube:

1. Open SQL Server Data Tools (SSDT) and then open the Adventure Works DW 2016 solution.
2. Double-click on the **Adventure Works DW** datasource view and then in the **Tables** pane (on the left) right-click in the empty area and select the **Add/Remove Tables...** option.
3. Find the **vReportItems** object in the list of **Available objects** on the left and double-click on it to move it to the right side, in the **Included Objects**. Then click **OK**.
4. In the **Solution Explorer**, right-click on the **Dimensions** folder and select the **New Dimension...** option.
5. Click **Next** if the wizard shows the introduction page. Then click **Next** again and then find the **vReportItems** object in the **Main table** drop-down list. It should be at the end.
6. Specify the **ID** column for the **Key column** and the **Name** column for the **Name column** and then click **Next**.
7. Mark the **Description** and **Parent ID** column as additional attributes, but uncheck the **Enable Browsing** option for **Description**. Rename it to **Report Item Description** and then click on **Next**.
8. Specify **Reporting Dimension** for the name of this dimension and click on **Finish**.
9. Now it's time to fine-tune the dimension and its attributes. Click on the dimension name in the **Attributes** pane, then fill the **Language** and **Collation** properties with values that match your regional settings, that is. **English (United States)** and **Latin 1_General, Accent sensitive**.
10. Click on the **ID** attribute and type **Attributes** for the **AttributeHierarchyDisplayFolder** property. Set the **OrderBy** property to **Key**.
11. Click on the **Parent ID** attribute and rename it to **Hierarchy**, then set the **Usage property** to **Parent**.
12. Set the **MembersWithData** property to **NonLeafDataHidden**.
13. Click on the **Naming Template** property and type in this: **Level 1;Level 2;Level 3; Level 4; Level 5**. The other option is to click on a small button for dialog and entering the word **Level** and a corresponding number in each line. Make sure you start with 1, not 2 as the **Level** column shows.

14. Process the dimension.
15. Once done, click on the **Browser** tab to show the dimension members. Expand them completely. It's a hierarchical structure with three levels (not counting the **All** member on the top). Now, turn on member properties by clicking on the button with that name (fourth button from the left), as shown:

The screenshot shows the 'Reporting Dimension.dim [Design]' window in the 'Adventure Works DW.dsv [Design]' environment. The 'Hierarchy' tab is selected. The 'Current level:' dropdown shows '(All)'. The hierarchy tree is expanded, showing two main categories: 'Internal Indicators' and 'Sales Indicators'. Under 'Internal Indicators', there are two members: 'Headcount' and 'Square Footage (in 000)'. Under 'Sales Indicators', there are five members: '# of Customers', '# of Orders', '# of Internet Orders', '# of Reseller Orders', and 'Reseller Sales (in 000)'. The 'Report Item Description' column provides details for each member. The 'Placeholder' entry is associated with the 'All' member and the 'Internal Indicators' category. The 'Number of employees' entry is associated with 'Headcount'. The 'Internet Orders + Reseller Orders' entry is associated with '# of Orders'. The 'Sales Indicators' category itself has no description. The other three members ('# of Customers', '# of Internet Orders', '# of Reseller Orders', and 'Reseller Sales (in 000)') all have 'Sales Indicators' listed in their descriptions.

Current level:	Hierarchy	Report Item Description
(All)		
All		Placeholder
Internal Indicators		Placeholder
Headcount	Internal Indicators	Number of employees
Square Footage (in 000)	Internal Indicators	
Sales Indicators		Placeholder
# of Customers	Sales Indicators	
# of Orders	Sales Indicators	Internet Orders + Reseller Orders
# of Internet Orders	# of Orders	
# of Reseller Orders	# of Orders	
Reseller Sales (in 000)	Sales Indicators	
Internet Sales (in 000)	Sales Indicators	
Product Sales (in 000)	Sales Indicators	

16. Double-click on the **Adventure Works** cube in the **Solution Explorer** and go to the **Dimension Usage** tab.
17. Click on the **Add Cube Dimension** button (third from left), select the **Reporting Dimension** in the dialog that opened, and then click on **OK**.
18. Verify that the dimension is successfully added to the cube, save it, and then deploy the solution.
19. Finally, note that the **Reporting Dimension** is not connected to any measure group. It will stay like that; this is not a mistake.

How it works...

The process of creating a reporting dimension was straightforward. We created a dimension based on the view that collects data from the Excel file. We designed it to be a parent-child dimension to support a, most probably, ragged (non-symmetrical in depth) structure of report items. We included the description so that we can have more information about a report item.

Report items in Excel have additional properties that we skipped in this recipe. The idea is to make things simple and to do everything step-by-step. In the following recipes, we will include those additional properties and make use of them.

There's more...

The default storage mode for dimension is MOLAP. Would it make more sense to make this a ROLAP dimension?

There are advantages and disadvantages in making the reporting a ROLAP dimension. The advantage is that a reporting dimension wouldn't need processing, so any metadata refreshes would instantly appear in dimensions when the result is refreshed in a pivot table or a report.

The disadvantage is the same-instant refresh. Imagine analyzing some data, making some changes in the pivot table and results suddenly look different because somebody modified the metadata.

Processing of such a small dimension doesn't take much, so the final verdict is to keep it as MOLAP and control who can process-update it and when. The metadata, on the other hand, can change many times between two processing (that is, for daily or hourly load) and that won't interfere the results. This way we add a separation between working on metadata and working on the cube. Of course, you may disagree and implement it as ROLAP, if you think that's better in your case.

Implementing custom rollups using MDX formulas

The reporting dimension created in the previous recipe is not connected to any measure group. That means it can't be used to display meaningful data. Yet.

Welcome custom rollups using MDX formulas!

Custom rollups are a way to tell dimension members what data to show. They are in fact MDX expressions that return a value. That value is displayed as the value of a member in the dimension. Each member can have its own expression, its own custom rollup. This expression, stored in a column in the relational table or a view, can be specified as the value of a certain property of any parent-child dimension. However, that only works when the dimension has a relationship with a fact table, with a measure group. In our case, it is not so. Our reporting dimension is completely loose, it can have any item as long as it has a formula for it. This flexibility comes at a price. We can't use the pre-build functionality of custom rollups, we have to invent our own.

This recipe shows how to implement *custom* rollups using MDX formulas.

Getting ready

Open the `Metadata.xlsx` file that you saved in the previous recipe and add the following data in the `Formula_MDX` column. The **ID** and the **Name** are just for the reference here:

ID	Name	Formula_MDX
S	Sales Indicators	
S01	# of Customers	[Measures].[Customer Count]
S05	# of Orders	[Measures].[Order Count]
S06	# of Internet Orders	[Measures].[Internet Order Count]
S07	# of Reseller Orders	[Measures].[Reseller Order Count]
S12	Reseller Sales (in 000)	[Measures].[Reseller Sales Amount]
S16	Internet Sales (in 000)	[Measures].[Internet Sales Amount]
S18	Product Sales (in 000)	[Measures].[Sales Amount]
I	Internal Indicators	

I01	Headcount	([Measures].[Amount], [Account].[Accounts].&[96])
I02	Square Footage (in 000)	([Measures].[Amount], [Account].[Accounts].&[99])

Save the file and close it. Then start SQL Server Management Studio and connect to your SQL Server 2016 *database engine* instance. Verify that the `[dbo]. [vReportItems]` view returns 11 rows when executed and that these new column entries are visible in it.

How to do it...

Follow these steps to implement custom rollups in the reporting dimension:

1. Open SQL Server Data Tools (SSDT) and then open Adventure Works DW 2016 solution.
2. In the **Solution Explorer**, double-click on the Reporting Dimension to open it.
3. Drag the `Formula_MDX` column from the `vReportItems` table in the **Data Source View** pane to the left, in the **Attributes** pane, to create a new attribute and name it **MDX Formula**.
4. Specify its **AttributeHierarchyEnabled** property as `False`.
5. Process the dimension.
6. Once done, click on the **Browser** tab to show the dimension members. Expand them completely. Turn on member properties as well.

Current level:	MDX Formula	Report Item Description
All		Placeholder
Internal Indicators		Number of employees
Headcount	([Measures].[Amount], [Account].[Accounts].&[96])	
Square Footage (in 000)	([Measures].[Amount], [Account].[Accounts].&[99])	
Sales Indicators		Placeholder
# of Customers	[Measures].[Customer Count]	
# of Orders	[Measures].[Order Count]	Internet Orders + Reseller Orders
# of Internet Orders	[Measures].[Internet Order Count]	
# of Reseller Orders	[Measures].[Reseller Order Count]	
Reseller Sales (in 000)	[Measures].[Reseller Sales Amount]	
Internet Sales (in 000)	[Measures].[Internet Sales Amount]	
Product Sales (in 000)	[Measures].[Sales Amount]	

7. Now, double-click on the **Adventure Works** cube in the **Solution Explorer** and go to the **Calculations** tab.
8. Create the MDX Formula measure:

```
Create Member CurrentCube.[Measures].[MDX Formula]
As
    [Reporting Dimension].[Hierarchy].CurrentMember
        .Properties('MDX Formula')
    ,Visible = 0
    ,Display_Folder = 'Reporting Measures';
```

9. Create the Value measure:

```
Create Member CurrentCube.[Measures].[Value]
As
    null
    ,Visible = 1
    ,Display_Folder = 'Reporting Measures';
```

10. Create the scope for Reporting Dimension and the Value measure:

```
Scope( [Measures].[Value] );
Scope( [Reporting Dimension].[Hierarchy].Members );
    This = iif( [Measures].[MDX Formula] = '', null,
                StrToValue(
                    ' Sum( [Reporting Dimension].[Hierarchy].[All], ' +
                    [Reporting Dimension].[Hierarchy]
                        .CurrentMember.Properties('MDX Formula') +' )'
                )
);
End Scope;
End Scope;
```

11. Now process the **Adventure Works** cube and then go to the **Cube Browser**, start Excel, and create a simple pivot table using Reporting Dimension and Fiscal Years. The report should look similar to the following screenshot. Yes, it's far from perfect, there are some errors inside, but the important thing is that its calculations are metadata-driven! We'll deal with corrections in the *There's more ...* section.

	A	B	C	D	E	F	G	H	I	J	K	L	M

16													

How it works...

First, we specified a relatively simple MDX expression in a column containing MDX formulas in our Metadata Excel file. Those were simple references to existing cube measures and tuples, to make things more interesting.

Once Excel was done, we modified the reporting dimension. We added a new property, named it **MDX Formula**, and later used this property in the cube, in the calculations, and to get the value of that property for each report item in that dimension.

We also created a special measure and named it the **Value** measure. The purpose of that measure is to display the value for each member of our reporting dimension.

The default value for the **Value** measure is the *null* value, which is specified in the definition of the measure. Furthermore, it is evaluated for items with formula only. A part of the scope statement evaluates the existence of the formula. In case there is no formula, we don't show any value.

The scope statement specifies what happens when a combination of the **Value** measure and report item occurs. In other words, we are restricting all the features to a very specific report.

In the end, the final evaluation of the expression is calculated by combining the `StrToValue()` function and the `Sum()` function with the initial expression.

The `StrToValue()` function is a standard MDX function that returns the value of a string expression which, of course, should be a valid MDX expression. It's great that MDX language has such a function, because that is what makes metadata-driven calculations possible in the first place.

The `Sum()` function, applied this way, is a small trick. It's not that we need to summarize anything. This function is there to override the current report item with the `All` member of that hierarchy. Remember, the reporting dimension is not related to any measure group. In other words, report items would return null for every expression. Only the root member contains a value, the value that we would like to get with the expressions. Therefore, the `Sum()` function forces the context in which the **MDX Formula** should be evaluated.

More information about the `StrToValue()` function can be found at:

<http://tinyurl.com/mdx-strtovalue>.

More information about why the `Sum()` function was used and not `ValidMeasure()`, or simply a tuple reference with the `All` member can be found in the following sections of this recipe.

There's more...

The pivot table had a few issues. We'll deal with them in this section.

The first thing we notice in the result is the error that appears in the **Grand Total** row. That error appears because it is an artificial member that doesn't exist in our **Metadata** Excel file, and hence doesn't have the **MDX Function** property. We can solve this problem in several ways, but the thing is that we don't need the total; we just need the report items. Therefore, we are going to disable it using an additional scope statement.

The same is true for the total for the columns. Although there are no errors in that column, we don't need that total, so we will disable it too.

Here's how the modified scope part should look like if we want to handle those issues:

```
Scope( [Measures].[Value] );
Scope( [Reporting Dimension].[Hierarchy].Members );
    This = iif( [Measures].[MDX Formula] = '', null,
                StrToValue(
                    ' Sum( [Reporting Dimension].[Hierarchy].[All], ' +
                    [Reporting Dimension].[Hierarchy]
                    .CurrentMember.Properties( 'MDX Formula' ) + ' )'
                )
);
;
```

```
End Scope;
Scope( Root( [Reporting Dimension] ) );
    This = null;
End Scope;
Scope( Root( [Date] ) );
    This = null;
End Scope;
End Scope;
```

The part where we removed grand totals is the part with the `Root()` function. We specified that we don't want to show any data for the top member of both the dimension reporting and the Date dimension.

After those modifications (and deployment of the cube) the pivot looks similar to the following screenshot. Yes, the **Grand Total** is still there (because we haven't disabled it in Excel options), but no values are shown there. It's up to us whether we want to hide it or not, in Excel pivot table options.

	A	B	C	D	E
1	Value	Column Labels ▾			
2	Row Labels	▼	+ FY 2011	+ FY 2012	+ FY 2013
3	Internal Indicators				
4	Headcount	648	1611	1988	952
5	Square Footage (in 000)	1256000	3354000	3297000	1382500
6	Sales Indicators				
7	# of Customers	1013	2685	9335	11342
8	# of Orders	1379	3765	12505	12935
9	# of Internet Orders	1013	2685	10955	13006
10	# of Reseller Orders	366	1080	1550	800
11	Reseller Sales (in 000)	8065435.305	25461971.49	32547674.92	14375515.27
12	Internet Sales (in 000)	3266373.657	6542788.276	9805009.748	9744505.54
13	Product Sales (in 000)	11331808.96	32004759.76	42352684.66	24120020.81
14	Grand Total				
15					
16					

True, we could have turned off grand totals in Excel immediately, but this is a much cleaner solution, it will work in all subsequently created pivots and no errors are shown in case the grand total is turned on.

Now that this is solved, let's see how else we can fix the values in the pivot. The next chapter deals with formatting the values, applying the multiplication factor, and similar enhancements.

Why not a built-in feature?

Custom rollups are usually implemented by specifying a column that contains MDX expressions in the `CustomRollupColumn` property of the parent key attribute. As explained in the introduction of this recipe, this wouldn't work because the dimension is not related to any measure group. That is, no measure can be used to automatically display report items values.

Try to implement this feature using the preceding property and by removing the scope part. See what happens when you reprocess the solution. Do you see any values? For any measure?

Why the Sum() function?

Reporting dimension is not related to any measure group. Somehow, we had to include the root member of that dimension in the final expression to be evaluated.

One option was to use the tuple expression. For example, if the original MDX formula was `[Measures].[Sales Amount]`, then a tuple would look like the following example:

```
( [Reporting Dimension].[Hierarchy].[All],  
[Measures].[Sales Amount] )
```

However, in case of an MDX formula containing numerical expression, such as `A+B`, where A and B are two measures, members, tuples, or whatever is valid in terms of MDX expressions, forming a tuple on top of it would result in an error. Tuples don't contain numerical expressions (values), they reference the cube's objects. Which means that we can't use tuples to extend the original MDX formula with the `All` member.

The other option was to use the `ValidMeasure()` MDX function. Again, that function has its limitation in terms of arguments that it accepts. Numerical expressions are again not allowed.

One MDX function that handles both tuples and numerical expressions is the `Sum()` function!

Its first argument is a set (or a member) and its second is a value (a measure or a numerical expression). The first argument states where the values should be calculated, over what to perform the sum. The second says how to calculate it, what's the formula, which is very convenient. We can use an MDX formula as the second argument and at the same time instruct the `Sum()` function to operate on the `All` member only. Since it's a single member, performing a sum over it is like saying *I have a list with one item only and I want to sum all the items I have*. As stated before, it's a trick that serves the purpose of establishing the context where the original MDX formula should be evaluated, always on the root member of unrelated dimension!

More complex formulas

Yes, it's possible to use more complex formulas for MDX expressions. The only condition is that those expressions evaluate to either a member, a tuple value, or similar; a set is not allowed as the result. They are allowed as an intermediate result inside the formula, which then must be shrunk to a single item, using, for example, a `Tail()` and `Item()` combination function to get the last member in a set.

Implementing format string, multiplication factor, and sort order features

In this recipe, we're going to learn how to enhance our reporting dimension.

Take one more look at the last screenshot in the previous recipe. You'll see that the values are not formatted at all. You might also notice that the sales figures were supposed to be in thousands, but they're not. Finally, we might have wanted to put the sales indicators on top and to always stick with the Internet and then Reseller report items, using the same order (see rows 8-11 in Excel in the screenshot).

Now that we know what the goal is, let's see how to do it, but first-let's put some entries in our `Report_Items` sheet.

Getting ready

Open the `Metadata.xlsx` file that you used in the previous recipes. Fill the following columns in it: `Sort_Order`, `Multiplication_Factor`, and `Format_String`.

ID	Name	Sort_Order	Multiplication_Factor	Format_String
S	Sales Indicators	4		NA
S01	# of Customers	1	1	,
S05	# of Orders	2	1	,
S06	# of Internet Orders	1	1	,
S07	# of Reseller Orders	2	1	,
S12	Reseller Sales (in 000)	5	1000	,##0
S16	Internet Sales (in 000)	4	1000	,##0
S18	Product Sales (in 000)	7	1000	,##0
I	Internal Indicators	5		NA
I01	Headcount	1	1	,
I02	Square Footage (in 000)	2	1000	,

Save the file and close it. Then start SQL Server Management Studio and connect to your SQL Server 2016 *database engine* instance. Verify that the view `[dbo]. [vReportItems]` returns 11 rows when executed and that these new column entries are visible in it.

How to do it...

Follow these steps to implement custom rollups in the reporting dimension:

1. Open SQL Server Data Tools (SSDT) and then open Adventure Works DW 2016 solution.
2. In the **Solution Explorer** double-click on the **Reporting Dimension** to open it.
3. Drag the **Format_String** column from the `vReportItems` table in the **Data Source View** pane to the left, in the **Attributes** pane, to create a new attribute `Format String` (SSAS automatically removes the underline in the name).

4. Do the same for these columns too: **Multiplication_Factor** and **Sort_Order**.
5. Turn both the Multiplication Factor and Sort Order attributes into properties by changing the **AttributeHierarchyEnabled** property to **False**.
6. Leave the Sort Order attribute as an attribute, but make it invisible by changing the **AttributeHierarchyVisible** property to **False**.
7. Set the **OrderBy** property for the Sort Order attribute to **Key**.
8. Now, find the **ID** attribute and set its **OrderBy** property to **AttributeKey**. Then set the **OrderByAttribute** property to the Sort Order attribute.
The **OrderByAttribute** property is just beneath the **OrderBy** property.
9. Process the dimension.
10. Once done, click on the **Browser** tab to show the dimension members. Expand them completely. Turn on new member properties.

The screenshot shows the 'Reporting Dimension.dim [Design]' tab in the SQL Server Data Tools interface. The 'Browser' tab is active. A table displays dimension members and their properties:

Current level:	Format String	Multiplication Factor	Sort Order
All	NA	0	1
Sales Indicators	#,#	1	1
# of Customers	#,#	1	2
# of Orders	#,#	1	1
# of Internet Orders	#,#	1	2
# of Reseller Orders	#,#	1	4
Internet Sales (in 000)	#,##0	1000	5
Reseller Sales (in 000)	#,##0	1000	7
Product Sales (in 000)	#,##0	1000	2
Internal Indicators	NA	0	1
Headcount	#,#	1	2
Square Footage (in 000)	#,#	1000	

11. Now, double-click on the **Adventure Works** cube in the **Solution Explorer** and go to the **Calculations** tab.

12. Create the **Format String** measure above the definition of the **Value** measure:

```
Create Member CurrentCube.[Measures].[Format String]
As
    [Reporting Dimension].[Hierarchy]
        .CurrentMember.Properties('Format String')
,Visible = 0
,Display_Folder = 'Reporting Measures';
```

13. Create the **Multiplication Factor** measure below the **Format String** measure:

```
Create Member CurrentCube.[Measures].[Multiplication Factor]
As
    [Reporting Dimension].[Hierarchy]
        .CurrentMember.Properties('Multiplication Factor')
,Visible = 0
,Display_Folder = 'Reporting Measures';
```

14. Extend the scope for Reporting Dimension created in the previous recipe with a few additional lines of code that set the format string and divide the value by the multiplication factor:

```
Scope( [Measures].[Value] );
Scope( [Reporting Dimension].[Hierarchy].Members );
    This = iif( [Measures].[MDX Formula] = '', null,
                StrToValue(
                    ' Sum( [Reporting Dimension].[Hierarchy].[All], ' +
                    [Reporting Dimension].[Hierarchy]
                        .CurrentMember.Properties( 'MDX Formula' ) + ' )'
                )
    /
    iif( [Measures].[Multiplication Factor] = 0, 1,
        [Measures].[Multiplication Factor]
    );
    Format_String(This) = [Measures].[Format String];
End Scope;
End Scope;
```

15. Process the **Adventure Works** cube and then go to the **Cube Browser**, start Excel, and create a simple pivot table using **Reporting Dimension** and **Fiscal Years** or use the one from the previous recipe.

	A	B	C	D	E	
1	Value	Column Labels ▾				
2	Row Labels	▼	+ FY 2011	+ FY 2012	+ FY 2013	+ FY 2014
3	▣ Sales Indicators					
4	# of Customers	1,013	2,685	9,335	11,342	
5	▣ # of Orders	1,379	3,765	12,505	12,935	
6	# of Internet Orders	1,013	2,685	10,955	13,006	
7	# of Reseller Orders	366	1,080	1,550	800

9	Reseller Sales (in 000)	8,065	25,462	32,548	14,376	
10	Product Sales (in 000)	11,332	32,005	42,353	24,120	
11	▣ Internal Indicators					
12	Headcount	648	1,611	1,988	952	
13	Square Footage (in 000)	1,256	3,354	3,297	1,383	
14	Grand Total					
15						
16						

16. Note the few things in the report. First, some values are reduced by 1000. Next, values are formatted using the thousand separators and there are no decimals. Finally, report items are sorted-**Internet Sales** comes in front of the **Reseller Sales** and the report starts with **Sales Indicators**. All in all, the report looks much better this way. It looks the way we specified in our Excel file. It's completely metadata-driven!

How it works...

For each report item in our **Metadata** Excel file, we specified format string, sort order, and multiplication factor in separate columns. Those columns were later used either as properties or attributes of the Reporting dimension.

The `Sort Order` attribute was hidden and then used to sort the key attribute. Here we've simply made use of the built-in functionality of SSAS that enables four types of sorting an attribute, one of them being the one we used-by another's attribute key.

Multiplication factor and format string were converted to properties not to increase the dimensionality of the cube. Then, in the cube, each of them was *converted* to a hidden measure, which was later used in the scope statement, to fine-tune the value being shown.

Since, multiplication factor can be null or 0, we took care of that, making the expression a bit more complex, but still easy enough to understand.

In the end, the report looked the way we specified in the the Excel.

There's more...

If you move your mouse over report items in the Reporting Dimension, a hint that appears will show you all the attributes and properties related to it. It's a convenient feature of Excel. This way you can verify, that is, the MDX formula (in case you made an error), verify the format string, sort order, multiplication factor, or read the description of the item. Everything that was exposed as visible in the dimension.

Tips and tricks

The ID or the Parent_ID columns are not shown in the hint. However, that can be solved relatively simple. Add those columns as new attributes in the Reporting Dimension, rename them (because they were already added in the dimension before), and make them hidden. Reprocess the dimension and the cube and verify that they are displayed in the hint. This trick can help you identify items with errors or bad results quickly.

Additional information

Metadata Excel's structure has many columns. We will use some of them in the following recipes, some we won't because this chapter would become huge to list all the possible examples. Read which other column names were specified there and feel free to add them in your Reporting Dimension as properties, fill them with values in Excel, reprocess the dimension and the cube, and verify that they appear in the hint too. It might give you an idea or two of what else you could do with metadata.

Implementing unary operators

Unary operators are a way to bypass custom rollups in parent-child dimensions. Custom rollups, either built-in or the ones we created one recipe before, use MDX expressions to calculate the value of a member that has it defined. Unary operators use a simple character, most commonly a +, -, or ~ sign to instruct SSAS how that member aggregates into its parent. A plus means it is added, minus subtracted, and ~ means it doesn't aggregate at all.

Look at the last screenshot in the previous recipe. Item # of Orders is the aggregated value of two of its children. However, all three of them, that item and its children have MDX expressions that tell which value to display. We can simplify this. Instead of specifying an MDX formula for # of Orders, we can simply put + unary operator for its children.

Let's test this!

Getting ready

Open the `Metadata.xlsx` file that you used in previous recipes. Fill in the **UnaryOperator** column based on the following table:

ID	Name	Unary Operator	Formula_MDX
S	Sales Indicators	~	
S01	# of Customers	~	[Measures].[Customer Count]
S05	# of Orders	~	
S06	# of Internet Orders	+	[Measures].[Internet Order Count]
S07	# of Reseller Orders	+	[Measures].[Reseller Order Count]
S12	Reseller Sales (in 000)	~	[Measures].[Reseller Sales Amount]
S16	Internet Sales (in 000)	~	[Measures].[Internet Sales Amount]
S18	Product Sales (in 000)	~	[Measures].[Sales Amount]
I	Internal Indicators	~	
I01	Headcount	~	([Measures].[Amount], [Account].[Accounts].&[96])
I02	Square Footage (in 000)	~	([Measures].[Amount], [Account].[Accounts].&[99])

Additionally, remove the expression in the `Formula_MDX` column for the **# of Orders** item.

Save the file and close it. Then start SQL Server Management Studio and connect to your SQL Server 2016 *database engine* instance. Verify that the view `[dbo].[vReportItems]` returns 11 rows when executed and that these new column entries are visible in it.

How to do it...

Follow these steps to implement custom rollups in the reporting dimension:

1. Open SQL Server Data Tools (SSDT) and then open Adventure Works DW 2016 solution.
2. In the **Solution Explorer**, double-click the **Reporting Dimension** to open it.
3. Find the **Hierarchy** attribute and click on the small button next to the **UnaryOperatorColumn** in the **Properties** pane.
4. Select the **UnaryOperator** column in the dialog that appears, then click on **OK**.
5. Additionally, drag the **Unary_Operator** column from the **vReportItems** table in the **Data Source View** pane to the left, in the **Attributes** pane, to create a new attribute, **Unary Operator**.
6. Turn the **Unary Operator** attribute into a property by changing the **AttributeHierarchyEnabled** property to **False**.
7. Process the dimension.
8. Once done, click on the **Browser** tab to show the dimension members. Expand them completely and turn on member properties.

Current level:	MDX Formula	Report Item Description	Unary Operator
All		Placeholder	~
Sales Indicators	[Measures].[Customer Count]		~
# of Customers			~
# of Orders		Internet Orders + Reseller Orders	~
# of Internet Orders	[Measures].[Internet Order Count]		+
# of Reseller Orders	[Measures].[Reseller Order Count]		+
Internet Sales (in 000)	[Measures].[Internet Sales Amount]		~
Reseller Sales (in 000)	[Measures].[Reseller Sales Amount]		~
Product Sales (in 000)	[Measures].[Sales Amount]		~
Internal Indicators		Placeholder	~
Headcount	([Measures].[Amount], [Account].[Accounts].&[96])	Number of employees	~
Square Footage (in 000)	([Measures].[Amount], [Account].[Accounts].&[99])		~

9. Notice that each member has a small icon, which tells us that the member is aggregated into its parent. The same can be read from the Unary Operator property.
10. Process the **Adventure Works** cube and then go to the **Cube Browser**, start the Excel, and create a simple pivot table using **Reporting Dimension** and **Fiscal Years**, or use the one from the previous recipe.

A	B	C	D	E	
1	Value	Column Labels			
2	Row Labels	+ FY 2011	+ FY 2012	+ FY 2013	+ FY 2014
Sales Indicators					
4	# of Customers	1,013	2,685	9,335	11,342
5	# of Orders				
6	# of Internet Orders	1,013	2,685	10,955	13,006
7	# of Reseller Orders	366	1,080	1,550	800
8	Internet Sales (in 000)	3,266	6,543	9,805	9,745
9	Reseller Sales (in 000)	8,065	25,462	32,548	14,376
10	Product Sales (in 000)	11,332	32,005	42,353	24,120
Internal Indicators					
12	Headcount	648	1,611	1,988	952
13	Square Footage (in 000)	1,256	3,354	3,297	1,383
14	Grand Total				
15					

11. Note that the **# of Orders** item is missing its values. The reason is that we deleted its MDX formula.
12. Now, double-click on the **Adventure Works** cube in the **Solution Explorer** and go to the **Calculations** tab.
13. Create the **Unary Operator** measure above the definition of the **Value** measure:

```
Create Member CurrentCube.[Measures].[Unary Operator]
As
    [Reporting Dimension].[Hierarchy]
    .CurrentMember.Properties('Unary Operator')
    ,Visible = 0
    ,Display_Folder = 'Reporting Measures';
```

14. Extend the scope for **Reporting Dimension** created in the previous recipe with a few additional lines of code that sets the rollup (instead of null) for members with no formula defined:

```
Scope( [Measures].[Value] );
Scope( [Reporting Dimension].[Hierarchy].Members );
    This = iif( [Measures].[MDX Formula] = '',
        RollupChildren(
            [Reporting Dimension].[Hierarchy].CurrentMember,
            [Measures].[Unary Operator]
        ),
        StrToValue(
            ' Sum( [Reporting Dimension].[Hierarchy].[All], ' +
            [Reporting Dimension].[Hierarchy]
            .CurrentMember.Properties( 'MDX Formula' ) + ' )'
        )
    /
    iif( [Measures].[Multiplication Factor] = 0, 1,
        [Measures].[Multiplication Factor]
    );
    Format_String( This ) = [Measures].[Format String];
End Scope;
End Scope;
```

15. Process the Adventure Works cube and refresh Excel.

	A	B	C	D	E
1	Value	Column Labels			
2	Row Labels		+ FY 2011	+ FY 2012	+ FY 2013
3	Sales Indicators				
4	# of Customers	1,013	2,685	9,335	11,342
5	# of Orders	1,379	3,765	12,505	12,935
6	# of Internet Orders	1,013	2,685	10,955	13,006
7	# of Reseller Orders	366	1,080	1,550	800
8	Internet Sales (in 000)	3,266	6,543	9,805	9,745
9	Reseller Sales (in 000)	8,065	25,462	32,548	14,376
10	Product Sales (in 000)	11,332	32,005	42,353	24,120
11	Internal Indicators

14	Grand Total				
15					
16					

16. Notice that the # of Orders item again has its value, unchanged.

How it works...

Unary operators were specified in the **Metadata** Excel file and as such used as a new hidden property of our Reporting Dimension. A hidden measure was created in the cube that returns this unary operator for each report item. That operator was used as a dynamic parameter to the `RollupChildren()` MDX function.

The `RollupChildren()` function was used for report items without formula. Previously, our scope statement simply returned a null value which made sense, since we relied only on MDX formulas to calculate items' value. With the introduction of unary operators this had to change.

So, instead of null value, we calculated a member's value based on its children and their unary operators. Children with + were added, children with ~ were skipped. There were no children with -, but if we had those, they would be added with a negative value, that is subtracted.

The `RollupChildren()` function uses two arguments. The first one is the member that is being calculated. The second one is the unary operator, which, as in this case, doesn't have to be a constant value. It can be an MDX expression and it usually is if we are referring to member's children or navigate elsewhere in the parent-child hierarchy.

There's more...

Steps 3 and 4 are not required. They show how to specify unary operators for a dimension that is connected to a measure group which is usually the case. Since our `Reporting Dimension` is not, we could skip those two steps and the solution would still work. The only thing that would change are the icons for members and since they look so cool, we didn't skip those steps.

Try to remove that `UnaryOperatorColumn` property on the `Hierarchy` attribute and see what happens when you reprocess the solution.

- Related recipes are all that follow and precede in this chapter

Referencing reporting dimension's members in MDX formulas

MDX formulas that were used in previous recipes referred to either existing cube measures or other dimension's members. There were no relations between report items themselves; each stood alone in the hierarchy. That is, until we introduced unary operators (in the previous recipe) and showed how to replace simple formulas with an operator.

Still, unary operators are very limited in what they support. As their name says, they are operators, not expressions. They can help us by not having to specify every formula in case the values can be rolled up from children. And that's it.

The other way to enhance the reporting dimension is to allow references to its members in MDX formulas. It makes perfect sense to do so. It is the end users who will eventually fill the metadata in Excel. They know their report items the best.

They might not know much about the cube and its objects (dimensions, measures, attributes, and so on), but if they see report items (in the MDM system, for example), they could create formulas based on the existing report items, whether they were created by them or someone else in IT. They know how to calculate one from the others.

The idea of this recipe is to show what needs to be done to support referencing Reporting Dimension's members in MDX formulas.

Getting ready

Open the `Metadata.xlsx` file that you saved in the previous recipe. Add one extra row in the **Report_Items** table using this data:

ID	S17
Name	Reseller vs Internet Sales Ratio
Sort_Order	6
Parent_ID	S
Reporting_Category	Sales Indicators
Unary_Operator	~
Multiplication_Factor	1
Format_String	#,##0.0
Calculation_Type	X
Formula_MDX	iif([Reporting Dimension].[Hierarchy].&[S16] = 0, null, [Reporting Dimension].[Hierarchy].&[S12] / [Reporting Dimension].[Hierarchy].&[S16])

Note that the formula now refers to reporting dimension members.

Save the file and close it. Then start SQL Server Management Studio and connect to your SQL Server 2016 *database engine* instance. Verify that the view `[dbo]. [vReportItems]` now returns 12 rows.

How to do it...

Follow these steps to implement custom rollups in the reporting dimension:

1. Open SQL Server Data Tools (SSDT) and then open the Adventure Works DW 2016 solution.
2. In the **Solution Explorer**, double-click on the **Reporting Dimension** to open it.
3. Process update the dimension.
4. Open the **Adventure Works** cube and go to the **Cube Browser**, start the Excel, and create a simple pivot table using **Reporting Dimension** and **Fiscal Years** or use the one from the previous recipe.

	A	B	C	D	E	F	G	H	I	J	K	L	
1	Value	Column Labels											
2	Row Labels		+ FY 2005	+ FY 2006	+ FY 2007	+ FY 2008	+ FY 2009	+ FY 2010	+ FY 2011	+ FY 2012	+ FY 2013	+ FY 2014	+ FY 2015
3	Sales Indicators												
4	# of Customers												
5	# of Orders												
6	# of Internet Orders												
7	# of Reseller Orders												
8	Internet Sales (in 000)												
9	Reseller Sales (in 000)												
10	Reseller vs Internet Sales Ratio	#VALUE!	#VALUE!	#VALUE!	#VALUE!	#VALUE!	#VALUE!	#VALUE!	#VALUE!	#VALUE!	#VALUE!	#VALUE!	#VALUE!
11	Product Sales (in 000)												
12	Internal Indicators												
13	Headcount												
14	Square Footage (in 000)												
15	Grand Total												
16													

5. Note that the **Reseller vs Internet Sales Ratio** item has errors.
6. Return to the Reporting Dimension.
7. Drag the **Calculation_Type** column from the **vReportItems** table in the **Data Source View** pane to the left, in the **Attributes** pane, to create a new attribute, **Calculation Type**.
8. Turn the **Calculation Type** attribute into a property by changing the **AttributeHierarchyEnabled** property to **False**.
9. Process the dimension.
10. Go back to the **Adventure Works** cube, **Calculations** tab.

11. Create the Calculation Type measure above the definition of the Value measure:

```
Create Member CurrentCube.[Measures].[Calculation Type]
As
    [Reporting Dimension].[Hierarchy]
    .CurrentMember.Properties( 'Calculation Type' )
,Visible = 0
,Display_Folder = 'Reporting Measures';
```

12. Extend the scope for Reporting Dimension created in the previous recipe with a few additional lines of code that fix the calculation for members whose formula refers to the reporting dimension, that is, which have calculation type X defined in their metadata:

```
Scope( [Measures].[Value] );
Scope( [Reporting Dimension].[Hierarchy].Members );
    This = iif( [Measures].[MDX Formula] = '',
        RollupChildren(
            [Reporting Dimension].[Hierarchy].CurrentMember,
            [Measures].[Unary Operator] ),
        iif( [Measures].[Calculation Type] = 'X',
            StrToValue(
                [Reporting Dimension].[Hierarchy]
                .CurrentMember.Properties('MDX Formula')
            ),
            StrToValue(
                ' Sum( [Reporting Dimension].[Hierarchy].[All], ' +
                [Reporting Dimension].[Hierarchy]
                .CurrentMember.Properties( 'MDX Formula' ) +
                ' )'
            )
        )
    )
/
iif( [Measures].[Multiplication Factor] = 0, 1,
    [Measures].[Multiplication Factor] );
Format_String(This) = [Measures].[Format String];
End Scope;
Scope( Root( [Reporting Dimension] ) );
    This = null;
End Scope;
Scope( Root( [Date] ) );
    This = null;
End Scope;
End Scope;
```

13. Process the Adventure Works cube and refresh the Excel.

A	B	C	D	E
1 Value	Column Labels			
2 Row Labels	▼ + FY 2011	+ FY 2012	+ FY 2013	+ FY 2014
3 □ Sales Indicators				
4 # of Customers	1,013	2,685	9,335	11,342
5 □ # of Orders	1,379	3,765	12,505	13,806
6 # of Internet Orders	1,013	2,685	10,955	13,006
7 # of Reseller Orders	366	1,080	1,550	800
8 Internet Sales (in 000)	3,266	6,543	9,805	9,745
9 Reseller Sales (in 000)	8,065	25,462	32,548	14,376
10 Reseller vs Internet Sales Ratio	2.5	3.9	3.3	1.5
11 Product Sales (in 000)	11,332	32,005	42,353	24,120
12 □ Internal Indicators				
13 Headcount	648	1,611	1,988	952
14 Square Footage (in 000)	1,256	3,354	3,297	1,383
15 Grand Total				
16				

14. Note that the **Reseller vs Internet Sales Ratio** has values.

How it works...

Reseller vs Internet Sales Ratio is the first measure in our **Metadata** Excel file that has an MDX formula referencing the Reporting Dimension members. Simply adding that item in the dimension didn't work, the **Value** measure returned an error.

The trick is that the `Sum()` function is an overkill here. In case MDX formula has references to reporting dimension's members, the sum is no longer needed. It interferes. In this case, we don't want to change the context. We want to calculate the value of a report item based on some already evaluated report items. No reference to the root member is needed here.

We took care of it using a property name called `Calculation Type`, and we used `X` in a signal to remove the `Sum()` function.

The initial part of the steps was the same as in previous recipes, adding a property in the dimension. It's a straightforward and easy to understand process.

There's more...

Since some formulas require adding the root member to adjust the context (using the `Sum()` function and some don't), a general advice is not to mix them. When a formula references report items, don't add other dimensions and measures in that expression. Simply create another row in the **Metadata** Excel file where you'll pre-calculate the other part that deals with the cube's dimensions and measures, name it adequately, and use it in other types of formulas, those referring to report items only.

This principle of building items on top of each other is also a good method of isolating things in metadata. As mentioned earlier, IT knows cube's measures and dimensions better than the end users. Let them create intermediate report items that end users can refer to in their formulas. On the other hand, end users know their calculations better than IT and it's often faster for them to implement or correct them by themselves. The metadata-driven calculations approach allows fast modification of calculations. The reprocessing of the `Reporting Dimension` is very fast, and most importantly, there's no need to change the cube's structure for new report items and their properties. Everything is based on metadata. Which is something both the IT and end users would appreciate.

Implementing the MDX dictionary

MDX expressions become complex easily. The syntax requires precise references to cube objects. Unique member names are long and tend to make expressions hard to follow. Members can appear in multiple hierarchies. All in all, it's a jungle for those not experienced with SSAS.

Additionally, MDX expressions can sometimes return a wrong value if the context is not established properly. It's easy to know something went wrong when they throw an error or return nulls, like in previous examples in this chapter. That's because the reporting dimension was not related to any measure group. But, when we reference a dimension, there is a small chance we are missing something related to forcing the proper context. It's normal.

It's a consequence of having a complex analytical system that can answer many questions relatively simply, using an expression instead of having to write a procedure, code, or report. It answers many queries and expressions however weird they are. It's up to us, SSAS professionals who write MDX expressions, to verify their correctness and to make them good enough for many combinations that can occur in the pivot tables and reports.

Metadata Excel uses MDX formulas to specify how report items should be calculated and evaluated. Having MDX formulas outside of the cube is a way to have a stable cube structure that requires rare modification because existing calculations can be changed outside, in a file such as **Metadata** Excel or in an MDM (Master Data Management) system and new calculations are easily added as new rows. Each calculation can be built on top of the other. All in all, it's a very interesting concept. So interesting that it makes sense to open it to end users and let them manage report items, their properties, and calculations. Because, in the end, it is them who will use that in their reports and pivot tables.

This chapter presents an idea of how to simplify the life of end users and how to enable them to enter formulas in a more user-friendly way. The answer lies in establishing the MDX dictionary!

Getting ready

Open the `Metadata.xlsx` file. Create a new sheet and name it `MDX_Dictionary`, then enter the following values in it and format it as a table with four columns:

Token	MDX_Expression	Type	Description
@current	CurrentMember	Function	Use when comparing members
@meas	[Measures]	Dimension	Use as a prefix for a measure
@value	[Measures].[Amount]	Measure	Financial amount
@item	[Reporting Dimension].[Hierarchy]	Hierarchy	Use when specifying report items
@fiscal	[Date].[Fiscal]	Hierarchy	Fiscal date prefix
@acc_id	[Account].[Accounts]	Hierarchy	Account ID reference
#is_acc_no	(Tail(Exists([Account].[Accounts].Members, [Account].[Account Number].&[#is_acc_no])).Item(0), [Measures].[Amount])	Tuple	Account book-keeping number reference

#bs_acc_no	(Tail(Exists([Account].[Accounts].Members, [Account].[Account Number].&[#bs_acc_no])).Item(0), [Measures].[Amount])	Tuple	Account book-keeping number reference
------------	---	-------	---------------------------------------

Then, go in the Report_Items sheet and add the following report items as new rows:

ID	Name	Sort_Order	Formula_User_Friendly	Formula_Description
IS	Income Statement	3		
IS_Rev	Revenue	1	#is_acc_no=4100	Net Sales
IS_Exp	Expenses	2	@item.&[IS_OPEX] + @item.&[IS_COGS]	
IS_COGS	COGS	3	#is_acc_no=5000	Total Cost of Sales
IS_GrossP	Gross Profit	4	@item.&[IS_Rev] – @item.&[IS_Exp]	
IS_OPEX	OPEX	5	#is_acc_no=60	Operating Expenses
IS_SGA	SGA Expenses	6	@item.&[IS_OPEX] – @item.&[IS_DA]	
IS_DA	DA	7	'#is_acc_no=680	Depreciation
IS_EBITDA	EBITDA	8	@item.&[IS_EBIT] + @item.&[IS_DA]	
IS_EBIT	EBIT	9	#is_acc_no=40	Operating Profit
IS_OtherIE	Other Incomes and Expenses	10	#is_acc_no=80	Other Income and Expense
IS_PBT	Profit before Tax	11	@item.&[IS_NetInc] + @item.&[IS_Tax]	
IS_Tax	Tax	12	#is_acc_no=8500	Taxes
IS_NetInc	Net Income	13	#is_acc_no=4	Net Income

Next, fill all these rows except the first one (where ID = IS) with these values:

Format_String	#,##0
Unary_Operator	~
Multiplication_Factor	1000
Parent_ID	IS

Then repeat the process by adding these rows too:

ID	Name	Sort_Order	Formula_User_Friendly	Formula_Description
BS	Balance Sheet	4		
BS_Assets	Total Assets	1	#bs_acc_no=10	Assets
BS_A_Curr	Current Assets	2	#bs_acc_no=110	Current Assets
BS_A_Cash	Cash	3	#bs_acc_no=1110	Cash
BS_A_AccRec	Accounts Receivable	4	#bs_acc_no=1120	Receivables
BS_A_Inv	Inventory	5	#bs_acc_no=1160	Inventory
BS_A_Fixed	Fixed Assets	6	#bs_acc_no=1200	Property, Plant, Equipment
BS_Debt	Total Debt	7	#bs_acc_no=20	Liabilities and Owners Equity
BS_Equity	Total Equity	8	#bs_acc_no=300	Owners Equity
BS_L_Curr	Current Liabilities	9	#bs_acc_no=2200	Current Liabilities
BS_L_LTerm	Long Term Liabilities	10	#bs_acc_no=2400	Long Term Liabilities

Next, fill all these rows except the first one (where ID = BS) with these values:

Format_String	#,##0
Unary_Operator	~
Multiplication_Factor	1000
Parent_ID	BS

Finally, put X in the **Calculation_Type** column and 1 in the **Multiplication_Factor** column (yes, replace 1000 with 1) for all report items that have the @item reference in their **Formula_User_Friendly** column. To help you identify them, we have them listed here:

ID	Name	Multiplication_Factor	Calculation_Type
IS_Exp	Expenses	1	X
IS_GrossP	Gross Profit	1	X
IS_SGA	SGA Expenses	1	X
IS_EBITDA	EBITDA	1	X
IS_PBT	Profit before Tax	1	X

Finally, save the **Metadata** Excel file and close it.

How to do it...

Follow these steps to combine the MDX dictionary with metadata in the Excel file:

1. Start SQL Server Management Studio and connect to your database instance.
2. Locate the Adventure Works DW 2016 database, click on it, and then click on the **New Query** button to open the Query Editor.
3. Create a select statement and execute it:

```
SELECT * FROM OPENQUERY( MetadataExcel,
    'SELECT * FROM [MDX_Dictionary$]' )
```

4. Replace the * in the inner select with the column names. You should be able to see the column names in the results.
5. Turn this into a view named `[dbo].[vMDXDictionary]` and save it in the Adventure Works DW 2016 database by executing it. Verify that the view is there and that it returns results without any errors.

6. Then, create a scalar-valued function in **Adventure Works DW 2016** database that does the translation of user-friendly expression into valid MDX expression using the MDX dictionary provided in the Excel file:

```
USE [AdventureWorksDW2016]
GO
CREATE FUNCTION [dbo].[TranslateToMDX]
( @expression nvarchar(255) )
RETURNS nvarchar(255)
AS
BEGIN
    SET @expression = REPLACE( @expression, '""', '' )
    SELECT @expression =
        CASE
            WHEN LEFT( @expression, 1 ) = '#' THEN
                CASE
                    WHEN CHARINDEX( '=', @expression ) > 0 THEN
                        CASE
                            WHEN LEFT( @expression,
CHARINDEX( '=', @expression ) - 1 ) = REPLACE(d.Token, '""', '' )
                                THEN
                                    REPLACE(d.MDX_Expression, d.Token, RIGHT( @expression,
LEN( @expression ) - CHARINDEX( '=', @expression ) ) )
                            ELSE @expression
                        END
                    END
                ELSE
                    REPLACE( @expression, d.Token, d.MDX_Expression )
                END
            END
        FROM [dbo].[vMDXDictionary] d;
    RETURN @expression
END
GO
```

7. Execute the function to store it in the database.
8. Then, modify the existing view `dbo.vReportItems`, so that it calls the `dbo.[TranslateToMDX]` function to translate what's in the **Formula_User_Friendly** column when the MDX formula is not available. The intention is also to preserve the original formula just in case:

```
ALTER VIEW [dbo].[vReportItems]
AS
SELECT
    [ID]
    , [Name]
```

```
, [Description]
, [Sort_Order]
, [Parent_ID]
, [Reporting_Category]
, [Level_of_Importance]
, [Unary_Operator]
, [Multiplication_Factor]
, [Unit_of_Measure]
, [Format_String]
, [Calculation_Type]
, [Formula_Flag]
, [Formula_MDX] AS [Formula_MDX_Original]
, CASE
    WHEN [Formula_MDX] <> '' THEN [Formula_MDX]
    ELSE [dbo].[TranslateToMDX]( [Formula_User_Friendly] )
END AS [Formula_MDX]
, [Formula_User_Friendly]
, [Formula_Description]
, [Is_Growth_Positive]
, [Status_Low]
, [Status_High]
, [Detailed_Report_URL]
FROM
OPENQUERY (MetadataExcel, 'SELECT * FROM [Report_Items$]' )
```

9. Execute the alter script and then execute the view to see how it works. It should return 37 rows. Verify that the translation works, that the **Formula_MDX** column is filled with MDX expressions for many rows. For all rows except placeholders and those with unary operator.
10. Now, open SQL Server Data Tools (SSDT) and in it the Adventure Works DW 2016 solution.
11. Process update the Reporting Dimension.
12. Start the Excel. Either create a simple pivot table using Reporting Dimension and Fiscal Years or refresh the one from the previous recipes.

13. Note that the Reporting Dimension displays new items that we added in this recipe and notice that although they didn't have any real MDX formulas, they are successfully displaying values. MDX translation works!

How it works...

The initial steps in this recipe took a while. It is because we were trying to make a good story and not to oversimplify it with a few report items only.

One thing that had to be prepared in advance is the MDX dictionary. Without it this recipe wouldn't work.

Look at the table with tokens and MDX expressions again. We provided a few entries to show the idea about it.

In it there are two types of tokens. Of course, you can think of additional types of tokens, but these two cover pretty much everything we needed. Tokens starting with the @ symbol are of one type, tokens starting with # are of the other. @tokens are replaced completely with the expression while # tokens get inserted inside the expression. To see this in action, simply open the `dbo.vReportItems` view and observe the **Formula_User_Friendly** and **Formula_MDX** columns.

The Type and Description columns are here for explanation only, no logic is implemented based on those columns.

The MDX dictionary is something a SSAS developer would prepare based on the types of expressions end users need when writing their calculations. End users should be familiar with the idea of two types of tokens and use them in the metadata in the **Formula_User_Friendly** column.

Now, look at the metadata we entered. Balance Sheet items had only one type of tokens, those with the # symbol. There you can see that immediately after the token there is a = symbol and the value that goes in expression. So, for tokens with # end users need to specify an ID, key, or similar, nothing else. That's very convenient. They can easily observe report items and their formulas and see if everything is fine or not. The complexity of the real MDX formula is taken away from them. It's in the dictionary. The SSAS developer created such an expression that establishes the right context and requires only a simple input parameter, which is something the end users specifies.

The expression for the Balance Sheet accounts says that for a certain business key (book-keeping account number, not the ID) the value Amount will be calculated. A simpler expression is presented in the previous two rows; that expression uses dimension ID. The expression is simple, but knowing which ID to use is a nightmare for end users. Moreover, if the data warehouse is reloaded from scratch, the IDs might not match the previous ones and all formulas would be wrong. So, SSAS developers took more effort to simplify the life of end users and let them use their IDs, that is, codes they are familiar with and codes that don't change. It's a similar effort the software designer for mobile phones took to enable customization and configuration of various settings for phone users. But those efforts pay off, users like the system designed that way. Hence the name user-friendly.

OK, back to the **Income Statement** items. There we have a combination of # and @ tokens. We already explained the # tokens. Let's just say that we could use the same token for Balance Sheet and Income Statement, but we decided to separate it. The expression is the same.

Tokens with @ are shortcut tokens. They replace a part of the MDX expression. Instead of having to write the full member name or a part of it, we can specify the token for it. We can combine @ tokens too, for example, @item.@curr would be translated to the current member of the Reporting dimension's hierarchy: [Reporting Dimension]. [Hierarchy]. CurrentMember.

Yes, end users would have to learn how to use tokens and some basic MDX expressions: forming tuples such as (x, y, z), using iif for branching or testing for nulls/zero, and comparing with the Is operator instead of =. But that's not so difficult and expression in metadata would suddenly look readable and easy to understand for them. They could manage them. Look how simple and meaningful the expressions for Balance Sheet and Income Statement items are. Now, compare that with our first metadata examples in this chapter. The expression for Headcount, for example. It refers to the ID. That account ID = 96 doesn't tell much what that expression will return, right? But those expressions in this recipe do, because they use business-related codes. MDX dictionary enabled that!

So much has been said about the MDX dictionary. By now, you probably understand what it's for, how to use it, and what extensibility it provides.

Once the metadata and MDX dictionary were in place, we created a view targeting the MDX dictionary. The view for report items already existed, but we had to modify it to include the call to a function. That function takes a user-friendly expression with tokens and processes it using MDX dictionary so that in the end an MDX expression pops out.

The function does a lot of string comparison, parsing, and replacements. Excel's cell sometimes have the ' symbol at their beginning. That is being stripped out immediately on the start. Next, we are evaluating whether we have a # token or not. In case we do, we replace the part of the expression with what comes after the = symbol. For @ tokens we simply replace the token with the corresponding MDX expression.

In the end, it's worth mentioning that the Report_Items sheet can contain values in both **Formula_User_Friendly** and the **Formula_MDX** columns. The latter one takes precedence, which is handled in the view. In other words, if there is an MDX formula, the dictionary is not used. Only when the MDX formula is missing, a user-friendly expression is translated using the dictionary. The rationale behind this? If the MDX formula is there, it's there for reason. Maybe the expression is very complex and cannot be handled using tokens. In any case, end users can delete that expression and write their friendly formula instead anytime.

There's more...

All report items have the same format string with no decimals. That makes the report value readable.

A few items in **Income Statement** had the value X in the **Calculation_Type** column. Those items use references to the reporting dimension, and therefore, as explained in the previous recipe, they have to be marked using the **Calculation Type** property in the dimension.

Additionally, those items take already reduced values (by 1000), which is the reason their **Multiplication Factor** is 1.

Next, both the **Income Statement** items and **Balance Sheet** items were flattened out. If that's not OK, adjust the parent IDs so that you can redesign the structure. That is, the end users can do that themselves.

As you saw, all report items have ~ for a unary operator. We didn't use unary operators (~ means not used, don't aggregate up). Formulas using MDX dictionary are simple, but powerful, and therefore make unary operators less appealing and required. The other thing is that unary operators prevent flattening of report items and flat report looks better for those who know what it consists of.

Finally, the numbers used in user formulas are alternate keys in dimension. Open the **dbo.DimAccount** table in SSMS and open the **Accounts** dimension in SSDT to verify that. Those alternate keys are codes that end users are familiar with.

Additional information

The beauty of MDX dictionary is that it's not hardcoded. You can specify your own *shortcuts* and phrases with parameters. Making sure that all tokens are unique and that one cannot be overlapped with another. That is, @acc and @acc_no wouldn't work because the first one would overwrite the second one. But @acc_id and @acc_no are perfectly fine. Even better, prefixes for tokens are also customizable. @ and # were used here as an example, but you can implement your own. Finally, if the MDX expression needs improvement, metadata and user friendly expressions can remain as is, SSAS developer can fix things *under the hood*, that is, expressions in the MDX dictionary.

Any modification in how the tokens operate, their prefixes, and similar requires modification of the scalar-valued function we created. Just make sure you don't forget that.

And yes, MDX dictionary belongs to the **Master Data Management (MDM)** system as well.

Tips and tricks

Add the **Formula_User_Friendly** column as a property in your dimension. Add the **Formula_Description** column and all other columns that would make sense. Now, end users will be able to see it in a hint.

- All recipes in this chapter are related, so make sure you read the whole chapter

Implementing metadata-driven KPIs

Metadata-driven calculations can be used for KPIs too. In SSAS, KPIs are like measures, except that each consists of four basic calculations: Value, Goal, Status, and Trend.

A common way to implement them is to define the name for a KPI and then those four calculations. If we go that way, we can have funny icons for Trend and Status calculations: traffic light, arrows, symbols, and so on. The other advantage of implementing KPIs using the built-in functionality of the cube is that we can combine them in a parent-child structure, which is a nice feature.

Of course, there is always the option to use normal calculated measures, four of them. In our case, that means to define three additional measures (since we already have the Value measure) and use them in reports. The advantage of that approach is that we can use properties that measures have, that is, background color and font color. Additionally, we can have more than three additional measures, we are limited by creativity only and what else can be shown. True, we lose icons and parent-child structure.

So, each approach has its pluses and minuses.

In the main part of this recipe, we are going to show how to implement metadata-driven KPIs using the built-in functionality. Other sections will shortly explain how to do it via regular calculated measures.

In any case, implementing metadata-driven KPIs is an interesting concept and if you follow the recipe through, you will find out why.

Getting ready

Open the `Metadata.xlsx` file, select the `Report_Items` sheet, and add the following report items as new rows in the existing table:

ID	Name	Formula_User_Friendly	Formula_Description
F	Financial Indicators		
L	Liquidity Ratios		
L1	Cash Ratio	iif(@item.&[BS_L_Curr] = 0, null, @item.&[BS_A_Cash] / @item.&[BS_L_Curr])	(Cash + Marketable Securities) / Current Liabilities
L2	Quick Ratio	iif(@item.&[BS_L_Curr] = 0, null, (@item.&[BS_A_Curr] - @item.&[BS_A_Inv]) / @item.&[BS_L_Curr])	(Current Assets – Inventory) / Current Liabilities
L3	Current Ratio	iif(@item.&[BS_L_Curr] = 0, null, @item.&[BS_A_Curr] / @item.&[BS_L_Curr])	Current Assets / Current Liabilities
AT	Asset Turnover Ratios		

AT1	Receivables Turnover	iif(@item.&[BS_A_AccRec] = 0, null, @item.&[IS_Rev] / @item.&[BS_A_AccRec])	Annual Credit Sales / Accounts Receivable
FL	Financial Leverage Ratios		
FL1	Debt Ratio	iif(@item.&[BS_Assets] = 0, null, (@item.&[BS_L_Curr] + @item.&[BS_L_LTTerm]) / @item.&[BS_Assets])	Total Liabilities / Total Assets
FL2	Debt-to-Equity Ratio	iif(@item.&[BS_Equity] = 0, null, @item.&[BS_Debt] / @item.&[BS_Equity])	Total Debt / Total Equity
P	Profitability Ratios		
P1	Gross Profit Margin	iif(@item.&[IS_Rev] = 0, null, (@item.&[IS_Rev] - @item.&[IS_COGS]) / @item.&[IS_Rev])	(Sales - COGS) / Sales
P2	ROA	iif(@item.&[BS_Assets] = 0, null, @item.&[IS_NetInc] / @item.&[BS_Assets])	Net Income / Total Assets
P3	ROE	iif(@item.&[BS_Equity] = 0, null, @item.&[IS_NetInc] / @item.&[BS_Equity])	Net Income / Shareholder Equity

Next, fill all the rows containing formula with these values:

Format_String	#,##0.00
Unary_Operator	~
Multiplication_Factor	1
Calculation_Type	X

Finally, fill other properties too:

ID	Name	Sort_Order	Parent_ID	Is_Growth_Positive	Status_Low	Status_High
F	Financial Indicators	5				
L	Liquidity Ratios	1	F			

L1	Cash Ratio	1	L	Yes	0.10	0.50
L2	Quick Ratio	2	L	Yes	0.90	1.00
L3	Current Ratio	3	L	Yes	1.50	2.00
AT	Asset Turnover Ratios	2	F			
AT1	Receivables Turnover	1	AT	Yes	0.60	1.00
FL	Financial Leverage Ratios	3	F			
FL1	Debt Ratio	1	FL	No	0.50	0.25
FL2	Debt-to-Equity Ratio	2	FL	No	5.00	1.50
P	Profitability Ratios	4	F			
P1	Gross Profit Margin	1	P	Yes	0.40	0.60
P2	ROA	2	P	Yes	0.02	0.05
P3	ROE	3	P	Yes	0.05	0.07

Finally, save the **Metadata** Excel file and close it.

How to do it...

Follow these steps to implement metadata-driven KPIs based on the metadata in the Excel file:

1. Start SQL Server Management Studio and connect to your database instance.
2. Locate the **Adventure Works DW 2016** database and then alter the existing view [dbo] . [vReportItems] in it, so that a few columns have proper data types:

```
ALTER VIEW [dbo].[vReportItems]
AS
SELECT
    [ID]
    , [Name]
    , [Description]
    , [Sort_Order]
    , [Parent_ID]
    , [Reporting_Category]
    , [Level_of_Importance]
    , [Unary_Operator]
```

```
, [Multiplication_Factor]
, [Unit_of_Measure]
, [Format_String]
, [Calculation_Type]
, [Formula_Flag]
, [Formula_MDX] AS [Formula_MDX_Original]
,CASE
    WHEN [Formula_MDX] <> '' THEN [Formula_MDX]
    ELSE [dbo].[TranslateToMDX]( [Formula_User_Friendly] )
END AS [Formula_MDX]
,[Formula_User_Friendly]
,[Formula_Description]
,[Is_Growth_Positive]
,CONVERT( FLOAT, [Status_Low] ) AS [Status_Low]
,CONVERT( FLOAT, [Status_High] ) AS [Status_High] ,
,[Detailed_Report_URL]
FROM
OPENQUERY (MetadataExcel, 'SELECT * FROM [Report_Items$]' )
```

3. Execute the alter script and then execute the view to see if it works. Verify the new rows that appeared.
4. Now, open SQL Server Data Tools (SSDT) and in it the Adventure Works DW 2016 solution, then double-click the Reporting Dimension to open it.
5. Drag the Is_Growth_Positive, Status_High, and Status_Low columns from the [vReportItems] table in the **Data Source View** pane to the left, in the **Attributes** pane, to create three new attributes: **Is Growth Positive**, **Status High** and **StatusLow**.
6. Set the AttributeHierarchyEnabled property to False for all three attributes.
7. Set the OrderBy property to Key for those three attributes.
8. Verify that the data type for the key column of the **Status High** and **Status Low** attributes is Double.
9. Process the dimension.

10. Once done, click on the **Browser** tab to show new dimension members. Expand them completely and turn on member properties.

The screenshot shows the 'Reporting Dimension.dim [Design]' browser tab selected. The interface includes tabs for Dimension Structure, Attribute Relationships, Translations, and Browser. The Browser tab is active, showing a hierarchical list of dimension members. The current level is set to '(All)'. The hierarchy tree includes categories like Sales Indicators, Internal Indicators, Income Statement, Balance Sheet, Financial Indicators, Liquidity Ratios, Asset Turnover Ratios, Financial Leverage Ratios, Profitability Ratios, and specific measures like Cash Ratio, Quick Ratio, Current Ratio, Receivables Turnover, Debt Ratio, Debt-to-Equity Ratio, Gross Profit Margin, ROA, and ROE. Each member has columns for 'Is Growth Positive' (Yes or No), 'MDX Formula' (e.g., iif([Reporting Dim...]), and 'Status High' and 'Status Low' values (e.g., 0.5, 0.1).

Current level:	(All)	Is Growth Positive	MDX Formula	Status High	Status Low
All					
Sales Indicators				0	0
Internal Indicators				0	0
Income Statement				0	0
Balance Sheet				0	0
Financial Indicators				0	0
Liquidity Ratios				0	0
Cash Ratio	Yes	iif([Reporting Dim...]	0.5	0.1	
Quick Ratio	Yes	iif([Reporting Dim...]	1	0.9	
Current Ratio	Yes	iif([Reporting Dim...]	2	1.5	
Asset Turnover Ratios				0	0
Receivables Turnover	Yes	iif([Reporting Dim...]	1	0.6	
Financial Leverage Ratios				0	0
Debt Ratio	No	iif([Reporting Dim...]	0.25	0.5	
Debt-to-Equity Ratio	No	iif([Reporting Dim...]	1.5	5	
Profitability Ratios				0	0
Gross Profit Margin	Yes	iif([Reporting Dim...]	0.6	0.4	
ROA	Yes	iif([Reporting Dim...]	0.05	0.02	
ROE	Yes	iif([Reporting Dim...]	0.07	0.05	

11. Note that new member properties are there, as well as the formula (translated from a user-friendly one).
 12. Now, go back to the **Adventure Works** cube, **Calculations** tab.
 13. Create three new measures above the definition of the **Value** measure:

```
Create Member CurrentCube.[Measures].[Is Growth Positive]
As
[Reporting Dimension].[Hierarchy]
.CurrentMember.Properties( 'Is Growth Positive' )
,Visible = 0
,Display_Folder = 'Reporting Measures';
```

```
Create Member CurrentCube.[Measures].[Status High]
As
    [Reporting Dimension].[Hierarchy]
    .CurrentMember.Properties( 'Status High' )
    ,Visible = 0
    ,Display_Folder = 'Reporting Measures';

Create Member CurrentCube.[Measures].[Status Low]
As
    [Reporting Dimension].[Hierarchy]
    .CurrentMember.Properties( 'Status Low' )
    ,Visible = 0
    ,Display_Folder = 'Reporting Measures';
```

14. Create three additional measures in the end of the MDX script: Value Prev Year, Status, Trend:

```
Create Member CurrentCube.[Measures].[Value Prev Year]
As
    iif( [Date].[Fiscal].CurrentMember.Level.Ordinal = 0, null,
    iif( [Date].[Fiscal].CurrentMember.Level.Ordinal = 1,
        ( [Measures].[Value],
            [Date].[Fiscal].CurrentMember.PrevMember ),
        ( [Measures].[Value],
            ParallelPeriod( [Date].[Fiscal].[Fiscal Year],
                1, [Date].[Fiscal].CurrentMember )
        )
    )
)
,
Visible = 0
,Display_Folder = 'Reporting Measures';

Create Member CurrentCube.[Measures].[Status]
As
    iif( [Measures].[Value] = 0, null,
    iif( [Measures].[Is Growth Positive] = 'Yes',
        Case
            When [Measures].[Value] -
                CoalesceEmpty( [Measures].[Status High], 0 ) >= 0
            Then 1
            When [Measures].[Value] -
                CoalesceEmpty( [Measures].[Status Low], 0 ) < 0
            Then -1
            Else 0
        End,
        Case
            When [Measures].[Value] -
                CoalesceEmpty( [Measures].[Status High], 0 ) <= 0
```

```
Then 1
When [Measures].[Value] -
    CoalesceEmpty( [Measures].[Status Low], 0 ) > 0
Then -1
Else 0
End
)
)
,Visible = 1
,Display_Folder = 'Reporting Measures';

Create Member CurrentCube.[Measures].[Trend]
As
iif( [Measures].[Value Prev Year] = 0 OR
    IsEmpty( [Measures].[Value] ), null,
    iif( [Measures].[Is Growth Positive] = 'Yes',
        Case
            When ( [Measures].[Value] -
                [Measures].[Value Prev Year] )
            /
                [Measures].[Value Prev Year] > 0
            Then 1
            Else -1
        End,
        Case
            When ( [Measures].[Value] -
                [Measures].[Value Prev Year] )
            /
                [Measures].[Value Prev Year] < 0
            Then 1
            Else -1
        End
    )
)
,Visible = 1
,Display_Folder = 'Reporting Measures';
```

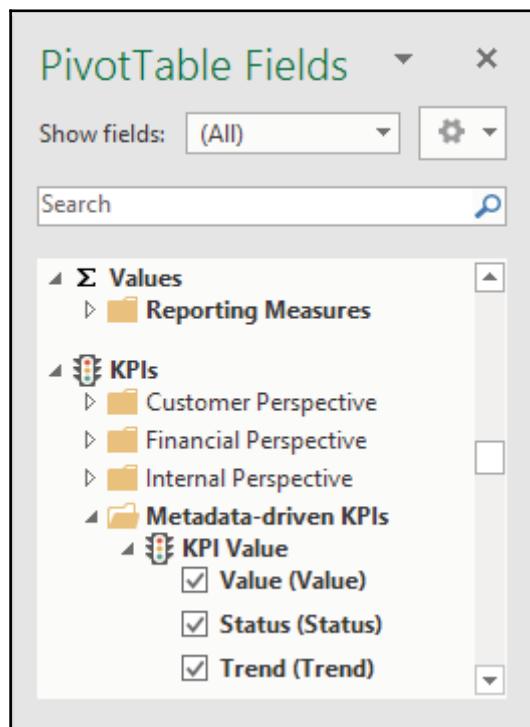

15. Process-full the cube.
16. Start the Excel. Either create a simple pivot table using Reporting Dimension and Fiscal Years or refresh the one from the previous recipes.

17. Notice that the Reporting Dimension displays new items that we added in this recipe.

	A	B	C	D	E
1	Value	Column Labels			
2	Row Labels		+ FY 2011	+ FY 2012	+ FY 2013
3	+ Sales Indicators				
4	+ Internal Indicators				
5	+ Income Statement				
6	+ Balance Sheet				
7	+ Financial Indicators				
8	+ Liquidity Ratios				
9	Cash Ratio	0.95	1.03	0.91	0.78
10	Quick Ratio	2.32	2.83	2.41	2.04
11	Current Ratio	3.23	3.92	3.49	3.02
12	+ Asset Turnover Ratios				
13	Receivables Turnover	0.74	0.57	0.61	0.64
14	+ Financial Leverage Ratios				
15	Debt Ratio	1.00	1.00	1.00	1.00
16	Debt-to-Equity Ratio	1.68	1.53	1.63	1.78
17	+ Profitability Ratios				
18	Gross Profit Margin	0.69	0.68	0.69	0.68
19	ROA	0.05	0.03	0.03	0.03
20	ROE	0.08	0.05	0.05	0.04
21	Grand Total				
22					

18. Go back to SQL Server Data Tools (SSDT) and in the KPIs tab of the cube's designer add a new KPI and name it KPI Value.
19. Specify [Measures].[Value] for the Value expression.

19. Specify **Shapes** for **Status indicator**. Specify **Standard arrow** for **Trend indicator**.
20. Specify [Measures]. [Status] for **Status expression**.
21. Specify [Measures]. [Trend] for **Trend expression**.
22. Type **Metadata-driven KPIs** for **Display folder**.
23. Deploy cube changes and refresh the Excel file with pivot.
24. Then locate the new KPI in the navigation pane and click on both **Status** and **Trend** fields.

25. The result will show KPIs and their status and trend information in the form of graphical elements. Optionally, change the text direction for **Status** and **Trend** columns to shrink the table.

	A	B	C	D	E	F	G	H	I	J	K	L	M

23														

How it works...

First, we had to add some data in the **Metadata** Excel file. We added few financial indicators whose user-friendly formulas referred to existing report items, those defined in the previous recipe. For that reason, they were marked **x** in the **Calculation_Type** column.

Beside the name, each item had a description roughly specifying how to calculate it and how to define its user-friendly formula. That helped in identifying existing report items' IDs and use those IDs in formulas. Formulas were very basic, except that the division by zero was taken care of using the `iif()` function.

Additionally, there were three new columns: `Is_Growth_Positive`, `Status_High`, and `Status_Low`. The first one was an indicator whether an increase in value is considered good or not. The other two specified a range for bad results and good results and what's left in between. Notice that for items where the growth is not appreciated, high and low values are swapped.

When this was done, the metadata was ready to be loaded into Reporting Dimension.

Three new attributes were easily added as properties in the dimension, but before this was done, a small correction in the view took care of data types.

Next, three corresponding measures were created in the MDX script, to be able to use them later in the calculations.

Additionally, three extra measures calculate the result in the same period of the previous year, status and trend.

The `Status` is a measure that defines whether the value is good or not. The `Trend` defines whether there is a positive or negative change compared to the same period in the previous year.

Both measures test the `Is_Growth_Positive` measure and based on that compare the values. Comparison for status is done based on metadata, using the `Status_High` and `Status_Low` measures. Comparison for trend is done based on the measure that calculates the value in the parallel period.

On the **KPIs** tab, we created a single KPI and defined the name, display folder, the value, status, and trend calculations. The value is simply pointing to our `Value` measure, the `status` to the `Status` measure, and `trend` to the `Trend` measure. Big expressions are specified in the MDX script on purpose so that the KPI part contains only simple pointers to existing calculated measures. That way all the complexity is either in a **Metadata** Excel file or in the MDX script.

Finally, when the `Value`, `Status`, and `Trend` components of the **KPI Value** KPI were added in the report in Excel, the result appeared.

There's more...

The other option to create KPIs (in a way) is to use calculated measures.

If you delete the KPI you created in this recipe (without deleting anything in the MDX script), and put the Value, Status, and Trend measures again in the pivot, the result will look similar, but there will be no icons. Instead, values -1, 0, and 1 will appear. That's because formulas are designed to return those values. However, we can modify the formulas to return something better, such as the value of increase or decrease over time (for Trend) or the difference between the Status_High and the actual value (absolute or relative). Or, we can use those -1, 0, and 1 values to color the font, that is, -1 being red, 0 being yellow, and 1 being green. Finally, we can use -1, 0, and 1 to define a format string, that is, + for 1, - for -1, = for the same, and blank for the rest.

We will now give an example.

Extend the bottom part of the Trend measure to include the format string as well:

```
,Visible = 1  
,Format_String = '"+"; "-"; "="; ""'  
,Display_Folder = 'Reporting Measures';
```

Next, extend the scope part for the Value measure to include the Fore_Color and Font_Flags assignments:

```
Format_String(This) = [Measures].[Format String];  
Fore_Color(This) = iif( [Measures].[Status] = 1,  
                      RGB(0, 165, 80),  
                      iif( [Measures].[Status] = -1,  
                           RGB(230, 32, 32),  
                           RGB(0, 0, 0) )  
                    );  
Font_Flags(This) = Abs( [Measures].[Status] );
```

Now, deploy the changes, refresh the Excel, and remove the Status measure. The result should look as follows:

	A	B	C	D	E	F	G	H	I
1		Column Labels							
2		+ FY 2011	+ FY 2012	+ FY 2013	+ FY 2014				
3	Row Labels	Value	Trend	Value	Trend	Value	Trend	Value	Trend
4	↳ Sales Indicators								
5	↳ Internal Indicators								
6	↳ Income Statement								
7	↳ Balance Sheet								
8	↳ Financial Indicators								
9	↳ Liquidity Ratios								
10	Cash Ratio	0.95		1.03	+	0.91	-	0.78	-
11	Quick Ratio	2.32		2.83	+	2.41	-	2.04	-
12	Current Ratio	3.23		3.92	+	3.49	-	3.02	-
13	↳ Asset Turnover Ratios								
14	Receivables Turnover	0.74		0.57	-	0.61	+	0.64	+
15	↳ Financial Leverage Ratios								
16	Debt Ratio	0.41		0.35	+	0.39	-	0.44	-
17	Debt-to-Equity Ratio	1.68		1.53	+	1.63	-	1.78	-
18	↳ Profitability Ratios								
19	Gross Profit Margin	0.69		0.68	-	0.69	+	0.68	-
20	ROA	0.05		0.03	-	0.03	-	0.03	-
21	ROE	0.08		0.05	-	0.05	-	0.04	-
22	Grand Total								
23									

As you can see, we can play with calculations and show data in interesting ways. We could even extend the metadata file to include colors and then refer to them in the calculations. The possibilities are endless.

Additional information

The Adventure Works 2016 OLAP database has several KPIs. They are hard-coded in the solution. What this recipe showed is that it doesn't have to be like that. We can remodel the solution and pivot it. Instead of having KPIs defined in the cube, we have them defined outside in the metadata and have a single KPI that works on all items. This way, end users can add new KPIs, modify the existing KPIs and change their properties and formulas any time they like and analyze the results instantly. This is an added value for them, because this architecture speeds up the development process of creating KPIs, maintaining them, and working with them in general.

Sure, you can have multiple KPIs defined in the **KPIs** tab of the cube designer, one for each display style. That is, one with gauges, the other with traffic lights, and so on. So, the user can choose a style for KPI, though all of them would return the same value since all of them would have exact calculations, only their properties such as `Trend indicator` and `Status indicator` would change.

Or, you can stick to calculated measures and have nothing in the **KPIs** tab. Simply by combining various calculated measures formatted and styled in an adequate way you could get interesting reports.

It's worth mentioning again, the update process is very simple. If there are new or modified items in metadata, a `ProcessUpdate` of dimension is sufficient and that's fast on such a small dimension! Not even that is required if its storage mode is ROLAP, then data refresh is instantaneous. However, if the metadata structure is modified (that is, you added several new columns and you need them in the dimension), then a `ProcessFull` is required.

Tips and tricks

You can enhance the existing metadata KPI calculations to include an area of tolerance for trends (defined in metadata), such as 2% plus or minus that is not considered a growth or a fall for trend, but simply an oscillation.

You can define additional calculations and use them to provide more information on each report item. Here are a few examples:

- Rolling average over last N months
- YTD, MTD value
- Targets (either metadata-based or calculated using an expression from the rest of the cube)
- Differences, both absolute and relative (to target, previous periods, ...)
- Warning (for crossing over metadata-based thresholds)

On the Edge

In this chapter, we will cover the following recipes:

- Clearing the Analysis Services cache
- Using Analysis Services stored procedures
- Executing MDX queries in T-SQL environments
- Using SSAS Dynamic Management Views (DMVs) to fast-document a cube
- Using SSAS Dynamic Management Views (DMVs) to monitor activity and usage
- Capturing MDX queries generated by SSAS frontends
- Performing a custom drillthrough

Introduction

The last chapter in this book is very special. We're going to talk about some topics that didn't fit into the previous chapters topics, where MDX mixes with other areas, such as performance tuning, executing MDX queries in a T-SQL environment, using SSAS Dynamic Management Views (DMVs) to query metadata of a cube, and SSAS's internal performance and resource. These areas will expand our horizon and motivate us to explore more.

We're starting with clearing the cache. Clearing the cache is an important technique when doing performance tuning; queries that run for a long time on a cold cache may be instant on a warm cache. To measure the effect of any changes you make to your cube or MDX calculations, having the same initial conditions is a must. The first recipe covers two techniques for clearing the cube cache, executing an XMLA command, and using a stored procedure from the **Analysis Services Stored Procedure Project (ASSP)**. The procedure from the ASSP project can clear both the Analysis Services cache and the Windows filesystem cache.

Stored procedures are another interesting area. Whether you have developer skills or not, there are cool stored procedures available in the community assemblies, which means you're only a step away from exploring the benefits that they bring to your project. The second recipe introduces the Analysis Services Stored Procedure Project (ASSP), which is an open source software project hosted on [CodePlex](#).

Using the technique of distributed queries, you can execute MDX queries inside the relational database environment. The third recipe, *Executing MDX queries in T-SQL environments*, explains the procedure and settings that enable the SQL Server to run distributed queries with or without a linked server.

Dynamic Management Views (DMVs) are another interesting area that is not yet thoroughly explored. They can be used to query the metadata of a cube, and SSAS's internal performance and resources. Everything is there in tabular format so that you can use it with great ease. Two recipes cover that topic, although there are plenty of useful examples to be explored by yourself once you get the initial boost.

When client tools generate MDX queries for you, you might want to know what these MDX queries look like. SQL Server Profiler is a tool that can be used to capture the exact MDX queries your users are running against the cube. These captured MDX queries are often used for troubleshooting and performance tuning purposes. We dedicate one recipe in this chapter to showing you how to use the SQL Server Profiler to capture the exact MDX queries that a client application is sending to the cube.

Drillthrough is a mechanism in SSAS that allows end users to select a single cell from a cube and retrieve a result set from the multidimensional model for that cell to get more detailed information. The Drillthrough mechanism allows us to explore the data stored in an SSAS cube regardless of the relational engine. Finally, the last recipe covers how to create an MDX query with DRILLTHROUGH capability.

Remember, these recipes are here to encourage you to explore further and go over the edge.

Clearing the Analysis Services cache

If you have a poorly performing query, you will review both the design of your cube and the MDX query, and test the performance of different scenarios. Having the same initial conditions for every test is a must. Only then can you truly measure the effect of any changes you make.

The problem in preserving the initial condition lies in the fact that Analysis Services caches the result of each query, making every subsequent query potentially run faster than it normally would.

Normally, caching is a great thing. Hitting a cached value is a goal we're trying to achieve in our everyday cube usage because it speeds up the result. Here, however, we're trying to do the opposite – we're clearing the cache on purpose to have the same conditions for every query.

This recipe introduces the process of clearing the cache. It begins by showing the standard way of clearing the Analysis Services cache and then continues by pointing out a way to also clear the Windows filesystem cache.

Getting ready

Start the SQL Server Management Studio and connect to your SSAS 2016 instance; then click on the **New XMLA Query** button.

Expand the **Databases** item in the **Object Explorer** so that you can see the **Adventure Works DW 2016** database and its **Adventure Works** cube.

In this example, we're going to show how to clear the cache for that cube.

How to do it...

Follow these steps to clear the Analysis Services cube cache:

1. Write the following XMLA query:

```
<Batch xmlns =
    "http://schemas.microsoft.com/analysisservices/2003/engine">
    <ClearCache>
        <Object>
            <DatabaseID></DatabaseID>
            <CubeID></CubeID>
        </Object>
    </ClearCache>
</Batch>
```

2. Right-click on the **Adventure Works DW 2016** database in the **Object Explorer** and select **Properties**:

General	
Read-Write Mode	ReadWrite
Name	Adventure Works DW 2016
ID	Adventure Works DW 2016
Description	
Create Timestamp	8/8/2016 3:26:08 PM
Last Schema Update	8/9/2016 12:16:08 AM
Last Update	8/9/2016 12:16:22 AM
Security Settings	
Data Source Impersonation Info	Default
Status	
Last Processed	8/9/2016 12:16:22 AM
Estimated Size	17.87 MB
Storage	
Storage Location	

3. Notice the ID property highlighted in the previous screenshot. Copy the value, close the **Database Properties** window, and paste it inside the **DatabaseID** tags:

```
<DatabaseID>Adventure Works DW 2016</DatabaseID>
```

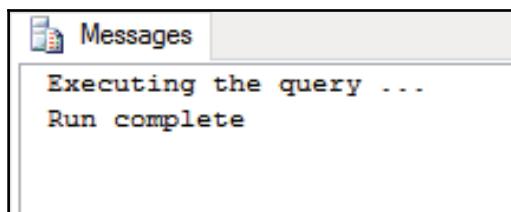

4. Now right-click on the **Adventure Works** cube in the **Object Explorer** and select **Properties**:

General	
Name	Adventure Works
ID	Adventure Works
Description	
Create Timestamp	8/8/2016 3:26:08 PM
Last Schema Update	8/9/2016 12:16:08 AM
Storage Location	
Processing Mode	Regular
Script Cache Processing Mode	Regular
Status	
State	Processed
Last Processed	8/9/2016 12:16:21 AM

5. Again, notice the `ID` property highlighted in the previous screenshot. Copy the value, close the **Cube Properties** window, and paste it inside the `CubeID` tags:

```
<CubeID>Adventure Works</CubeID>
```

6. To run the XMLA query, right-click on the **Adventure Works DW 2016** database; then choose **New Query** and then **XMLA**. If everything goes fine, you should see the result as shown in the following screenshot. The cube cache is successfully cleared.

How it works...

The `ClearCache` command clears the Analysis Services cache for the object specified in the command.

Several objects can be used inside that command. A common scenario is to use the cube object, as in this example. Other objects can be also specified. We will discuss that later in this recipe.

Inside the `ClearCache` command, we had to specify the object's ID, a property that uniquely identifies the object (among its sibling objects only, not on the entire SSAS instance). The ID is not visible in the **Object Explorer**, only the object's name. When we need the ID, we have to open the **Properties** window for that object.

The uniqueness of the object on the entire SSAS instance is enforced by the requirement to specify all parent objects up to the database object and include the object itself. That's why we had to specify both `DatabaseID` and the `CubeID` in this example.

If the query returns no errors, this means that it has successfully cleared the Analysis Services cache for that object.

There's more...

Clearing the Analysis Services cache is not enough to guarantee the same performance testing conditions. There's also the filesystem cache, which in turn consists of the Active Cache and the Standby Cache. To test MDX query performance on a true cold cache, we have to either reboot the server or clear those caches. Greg Galloway, one of the reviewers of this book, wrote a breakthrough article about it, which can be found at <http://tinyurl.com/GregClearCache>.

There are several ways, according to that article, on how you can clear those caches. One of them (and probably the most convenient one) is by using the `ClearAllCaches` stored procedure from the **Analysis Services Stored Procedure Project (ASSP)**.

The next recipe shows how to register an assembly and use its stored procedures on the Analysis Services server. The example will feature the `ClearAllCaches` stored procedure of the Analysis Services Stored Procedure Project, a procedure which clears both the Analysis Services cache and the filesystem cache (Active and Standby). Here's a link to that site:

<http://tinyurl.com/ASSPCodePlex>.

Once you register `ASSP.dll` on your server (or database), call the procedure (in the MDX query window) as follows:

```
call ASSP.ClearAllCaches()
```

There can be permission issues with clearing the cache depending on the identity of the caller. It is well documented on the ASSP site.

If you get a permission error, you can close SSMS and start it again with the **Run as Administrator** option. Then calling the `ClearAllCaches()` function should work without problems, if the administrator has the appropriate permissions to the Adventure Works DW 2016 database.

Objects whose cache can be cleared

Cube is just one of the four objects whose cache can be cleared. The other objects are database, measure group, and dimension. The appropriate commands are as follows:

- Database:

```
<Batch xmlns =
"http://schemas.microsoft.com/analysisservices/2003/engine">
```

```
<ClearCache>
  <Object>
    <DatabaseID>Adventure Works DW 2016</DatabaseID>
  </Object>
</ClearCache>
</Batch>
```

- Measure group:

```
<Batch xmlns =
  "http://schemas.microsoft.com/analysisservices/2003/engine">
  <ClearCache>
    <Object>
      <DatabaseID>Adventure Works DW 2016</DatabaseID>
      <CubeID>Adventure Works</CubeID>
      <MeasureGroupID>Sales Summary</MeasureGroupID>
    </Object>
  </ClearCache>
</Batch>
```

- Dimension:

```
<Batch xmlns =
  "http://schemas.microsoft.com/analysisservices/2003/engine">
  <ClearCache>
    <Object>
      <DatabaseID>Adventure Works DW 2016</DatabaseID>
      <DimensionID>Dim Product</DimensionID>
    </Object>
  </ClearCache>
</Batch>
```

Simply insert the ID of the object between its tags. All the IDs can be found in the **Properties** windows for only those objects, except for the measure groups' object. The **Properties** window is not implemented for them. Luckily, that's the only object where it is allowed to use both the name and the ID without getting an error.

If you still want to use the ID for measure groups, right-click on the measure group in the **Object Explorer** and go to **Script Measure Group As | DELETE To | New Query Editor Window**. There, you'll find the ID for that measure group: Fact Sales Summary.

Use the **CREATE To** or **ALTER To** option instead of the **DELETE To** option and you'll wait a bit longer for the script to appear.

You can use this trick for any object. Just make sure you don't run the **DELETE** query!

Or, play it safe by sticking to the **Properties** window as explained earlier.

Additional information

The following MDX query is recommended as the next step immediately after you clear the cache:

```
SELECT {} ON 0  
FROM [Adventure Works]
```

It forces the loading of the MDX script of the cube specified in the query. It also means that no data is loaded in the cache unless the MDX script has named sets, which, to be evaluated, require evaluation of measures. In that case, some data could be loaded into the cache.

Tips and tricks

In this recipe, we have chosen to execute the XMLA command in the XMLA Query Editor in SSMS. In fact, the XMLA command can also be executed from the MDX Query Editor in SSMS.

Like any other XML editor, the XMLA Query Editor will color-code the script using a color scheme and allow you to collapse nested elements and expand other ones. That's why we've used the XMLA Query Editor in this example.

This is also applicable to stored procedures.

- The related recipe is *Using Analysis Services stored procedures*

Using Analysis Services stored procedures

Analysis Services supports both COM and CLR assemblies (DLL files) as an extension of its engine, in which developers can write custom code. Once written and compiled, assemblies can be deployed to an Analysis Services instance.

Though the process of creating the assemblies is outside the scope of this book, using them is not, because of the benefits they bring you. The stored procedures implemented in those assemblies can be called from MDX queries, used in calculations, or triggered when an event occurs on the server.

If you haven't already read the previous recipe, do it now, because this recipe picks up where the previous one ended. It shows you how to register a popular open source assembly from the Analysis Services Stored Procedure Project (ASSP).

The first part of this recipe focuses on the `ClearAllCaches()` function stored procedure which clears both the Analysis Services cache and the filesystem cache, therefore allowing BI developers and testers to perform an accurate query tuning.

For those of you who want to learn more about how to include ASSP stored procedures as part of an MDX query, we will also illustrate this type of stored procedure in the later sections of this recipe.

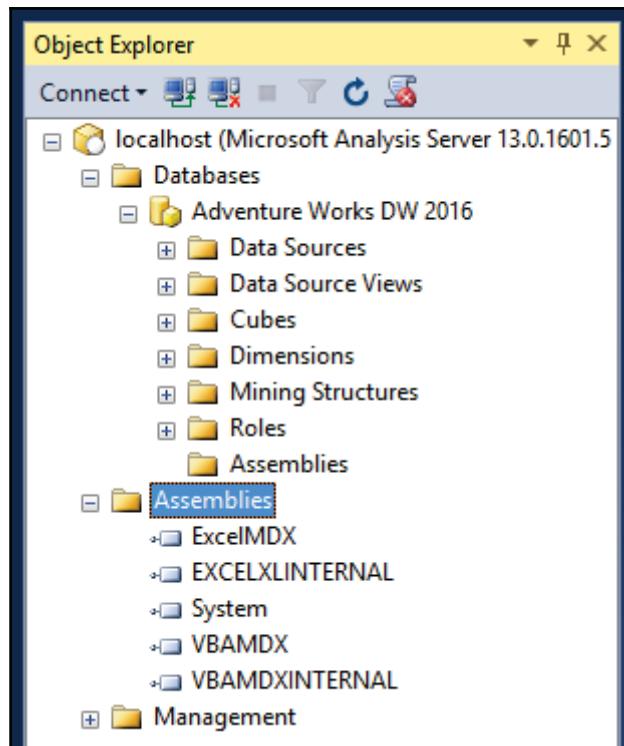

Are you ready to learn more? Then read on!

Getting ready

Start the SQL Server Management Studio and connect to your SSAS 2016 instance.

Expand the **Databases** item in the **Object Explorer** so that you can see the Adventure Works DW 2016 database. Expand the database and its **Assemblies** folder. It should be empty. No assemblies are registered there.

Now, expand the Assemblies folder of the server as displayed in the following screenshot:

These assemblies, deployed and registered on the server during the installation, are available to the entire SSAS instance.

Let's see how to register a new assembly on this server.

As mentioned in the introduction, we're going to use the *Analysis Services Stored Procedure Project* assembly, which can be downloaded from <http://tinyurl.com/ASSPCodePlex>.

Currently, the Analysis Services Stored Procedure Project has only a beta version for SSAS 2016 – the 1.4.0 release. We are going to use this version. You, on the other hand, are invited to try the stable release for SSAS 2016 if it exists.

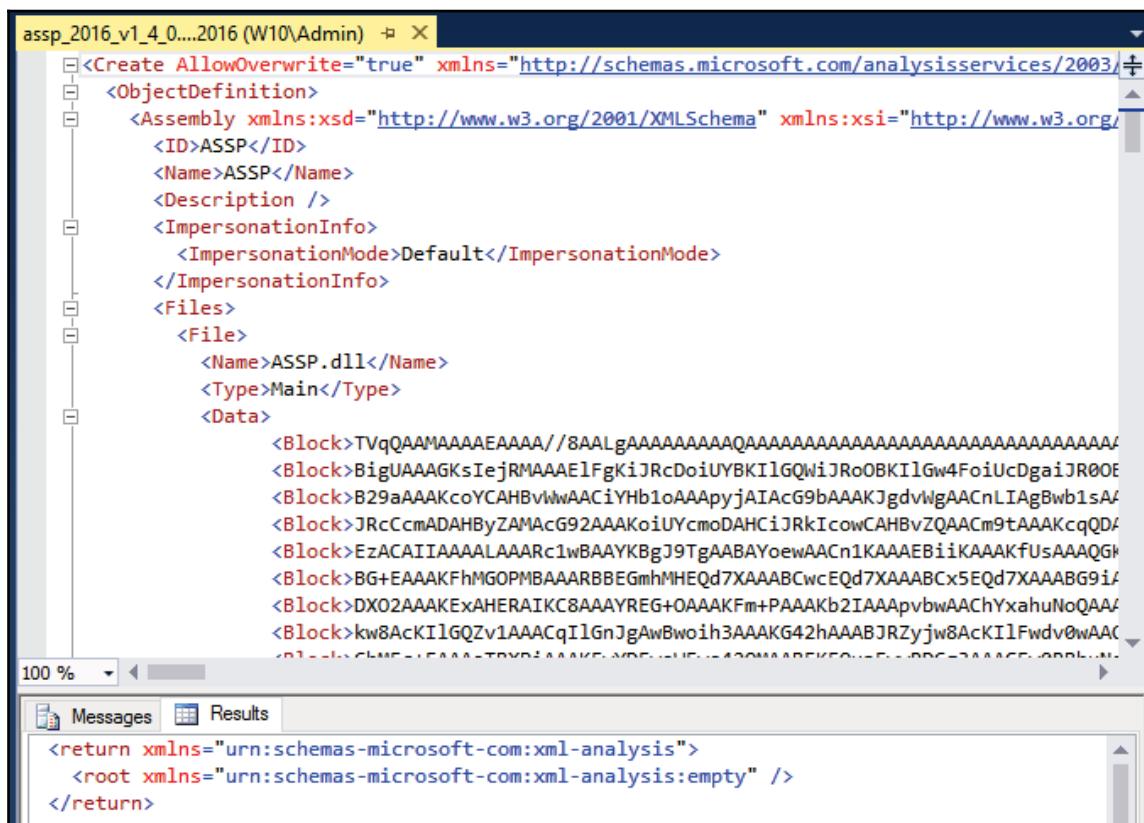

Download and save the XMLA file somewhere on your server (for example, to a folder such as C:\SSAS_Assemblies).

You're now ready to begin.

How to do it...

Follow these steps to add a custom assembly to the Analysis Services instance:

1. Load the downloaded XMLA file in **SQL Server Management Studio** by either double-clicking on it or loading it using the **File | Open | File...** menu option.
2. If you're being asked about the instance, choose your SSAS 2016 instance and click on the **OK** button.
3. Once the XMLA file is loaded into SSMS, click on the **Execute** button so that the XMLA script executes.
4. If everything goes well, you should see a screen like this:

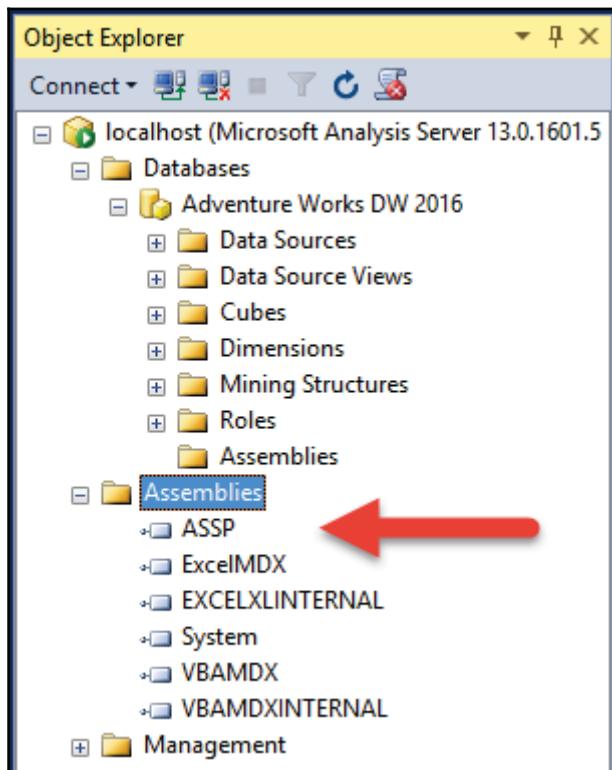

The screenshot shows the SQL Server Management Studio interface with the following details:

- Title Bar:** assp_2016_v1_4_0...2016 (W10\Admin)
- Object Explorer:** Shows the XMLA script structure:

```
<Create AllowOverwrite="true" xmlns="http://schemas.microsoft.com/analysisservices/2003/+/>
<ObjectDefinition>
  <Assembly xmlns:xsd="http://www.w3.org/2001/XMLSchema" xmlns:xsi="http://www.w3.org/+
    <ID>ASSP</ID>
    <Name>ASSP</Name>
    <Description />
    <ImpersonationInfo>
      <ImpersonationMode>Default</ImpersonationMode>
    </ImpersonationInfo>
    <Files>
      <File>
        <Name>ASSP.dll</Name>
        <Type>Main</Type>
        <Data>
          <Block>TVqQAMAAAAEAAAA//8AALgAAAAAAAAQAAAAAAAAAAAAAAAAAAAAAAAAAAAAAA
          <Block>BigUAAAGKsIejRMAAElFgKiJRCDoiUYBKILGQWiJR0BKILGw4FoiUcDgaiJR0OE
          <Block>B29aAAAKcoYCAHBvNwAACiYHb1oAAAPyjAIACg9bAAAKJgdvWgAACnLIAgBwb1sA/
          <Block>JRCCcmADAHByZAMAcg92AAAKoiUYcmoDAHCiJRkIcowCAHBvZQACm9tAAAKcqQD/
          <Block>EzACAIIAAAALAAARc1wBAAYKBgJ9TgAABAYoewAACn1KAAAEBiikAAAKfUsAAAQGk
          <Block>BG+EAAAKFhMGOPMBAAARBEGmhMHEqd7XAAABCwcEQd7XAAABCx5Eqd7XAAABG9i/
          <Block>DXO2AAAKExAHERAIKC8AAAYREG+OAAAKFm+PAAAKb2IAAApvbwAAChYxahuNoQAA/
          <Block>kw8AckI1GQzv1AACqIlGnJgAwBwoih3AAAKG42hAAABJRZyjw8AckI1Fwdv0wAAC
          <Block>CJUe+EAAL+TxDI2AAAEK+VQd7XAAABCw5Eqd7XAAABCx5Eqd7XAAABG9i/
```
- Status Bar:** 100 %
- Bottom Navigation:** Messages, Results
- Results Grid:** Shows the XML response from the server:

```
<return xmlns="urn:schemas-microsoft-com:xml-analysis">
  <root xmlns="urn:schemas-microsoft-com:xml-analysis:empty" />
</return>
```

5. The assembly will be visible in the list of server assemblies when you refresh it, which means you're ready to use it:

6. Now start a new MDX query by right-clicking on the **Adventure Works DW 2016** database in the **Object Explorer** and selecting the **New Query** button and then **MDX**.
7. Type this and then execute it:

```
call ASSP.ClearAllCaches()
```

Execution of the managed stored procedure `ClearAllCaches` failed with the following error: Exception has been thrown by the target of an invocation. `NtSetSystemInformation (SYSTEMCACHEINFORMATION)` error.

Not all privileges or groups referenced are assigned to the caller.

If you get this error, you can close SSMS and start it again with the **Run as Administrator** option. Then, calling the `ClearAllCaches` function should work without problems if the administrator has the appropriate permissions to the Adventure Works DW 2016 database.

8. The query might take a while to complete. Once it finishes, the result should say that the run is complete.
9. You're done! You have successfully registered a custom assembly and tested it, proving that it works by clearing all caches, that is, both the Analysis Services cache and the filesystem cache.

How it works...

An Analysis Services assembly can be registered two ways.

If the source file is an XMLA file as in this example, you simply load it into SSMS and execute it; then verify that it is successfully registered in the list of assemblies and optionally set up its properties there.

The other option is to register the `.dll` file. The `.dll` files are registered by clicking on the **Assemblies** folder and selecting the **New Assembly...** option. There you click on the button next to the **File Name** box and navigate to the file. Make sure the file is unblocked (see the properties of the `.dll` file in Windows Explorer). Once the file is selected, you can change the name of the assembly or its properties, for example, set the **Permission** option to **Unrestricted** if the company policy allows you to. Otherwise, some functions will be unavailable. The ASSP home page on [CodePlex](#) lists the permissions that are required by each of the functions. Optionally, add a description for this assembly so that you know what it does. Once you're done, you're ready to use the assembly and the procedures that it implements.

The assembly can be registered as a server-based assembly or as a database-specific assembly. Stored procedures in the server-based assembly can be used in any database on that SSAS instance. Database-specific assemblies can be used only in the database they've been registered at.

Some procedures can be activated using the `call` method, and others as part of a query or calculation, depending on the result they return. In this recipe, we've used a procedure that executes a specific task; that's why we used the `call` method. In the following section, we'll show how to use stored procedures as part of the query.

There's more...

Here's an MDX query; actually, there are two of them separated with a `GO` statement. Run them in SSMS:

```
WITH
MEMBER [Measures].[Sales Amount $] AS
    [Measures].[Sales Amount],
    BACK_COLOR = RGB(255, 255, 200)
SELECT
    NON EMPTY
        { [Date].[Fiscal].[Fiscal Year].MEMBERS } *
        { [Measures].[Sales Amount $],
            [Measures].[Gross Profit Margin] } ON 0,
    NON EMPTY
        { [Sales Territory].[Sales Territory Country]
            .[Sales Territory Country].MEMBERS } ON 1
FROM
    [Adventure Works]
CELL PROPERTIES
    VALUE,
    FORMATTED_VALUE,
    BACK_COLOR
GO

WITH
MEMBER [Measures].[Sales Amount $] AS
    [Measures].[Sales Amount],
    BACK_COLOR = RGB(255, 255, 200)
SELECT
    NON EMPTY
        Hierarchize(
            ASSP.InverseHierarchility(
                { [Date].[Fiscal].[Fiscal Year].MEMBERS } *
                { [Measures].[Sales Amount $],
                    [Measures].[Gross Profit Margin] } ) ) ON 0,
    NON EMPTY
        { [Sales Territory].[Sales Territory Country]
            .[Sales Territory Country].MEMBERS } ON 1
FROM
```

```
[Adventure Works]
CELL PROPERTIES
    VALUE,
    FORMATTED_VALUE,
    BACK_COLOR
```

The first MDX query contains a cross join of fiscal years and measures. In the second, the cross join is reversed using the `ASSP.InverseHierarchility()` stored procedure. This function reverses the order of the members within each tuple in the set, while keeping the order of the set unchanged. Now we have the measures displayed first in columns, and the fiscal years after the measures.

The result is still not appealing enough in this case. We want to group measures so that **Gross Profit Margin** and **Sales Amount \$** are displayed separately for all fiscal years. We achieved this by applying the `MDX.Hierarchize()` function. This MDX function orders the members of a set in a hierarchy. Finally, the columns are organized by **Gross Profit Margin** and **Sales Amount \$**:

Top Table Columns:

- FY 2010

United States	9.60%	5.28%	5.40%	11.99%	\$7,263,823.72	\$21,128,430.58	\$23,053,185.15	\$11,552,151.28

This example showed you how to use a stored procedure inside an MDX query. We can apply it directly on a set or an axis, or use other functions on top of it. The same is true for using procedures in MDX calculations. Try it!

Tips and tricks

A good practice in creating custom SSAS assemblies is to create a procedure that returns all the available stored procedures in that assembly, if there are many of them. This way you don't have to look at the documentation, as it is right there in front of you.

The ASSP assembly incorporates such a procedure. It should be called as follows:

Call ASSP.ListFunctions()

If the `ListFunctions()` is called with no parameters, it will return the functions available in all the .NET assemblies located at the server level.

If you need all the assemblies located in a specific database, you can call the function with the name of the specific database., for example, `CALL ListFunctions("Adventure Works DW")`.

The output should be as follows:

Assembly	Class	Method	ReturnType	Parameters
ASSP	TraceEvent	Fire TraceEventAndReturnValue	Int32	value as Int32
ASSP	Sets	AsymmetricSet	Set	member1 as Member, member2 as Member, member3 ...

Existing assemblies

Analysis Services also supports **Microsoft Visual Basic for Applications (VBA) COM Assemblies**. VBA COM Assemblies are registered automatically.

It's worth repeating one more time—that VBA functions are available to any cube once the SSAS instance is started.

VBA functions evaluate much more slowly than regular MDX functions. The SSAS team assessed the often-used VBA functions and implemented them as part of the SSAS code base. These functions have better performance than the other functions, and hence can be considered as *internal VBA functions*.

SSAS-supported VBA functions are listed in VBA functions in MDX and DAX (<http://tinyurl.com/VBAinMDX>).

Excel functions, although registered, are unavailable unless Excel is installed on the server. Only when Excel is installed do they become valid and applicable.

There are other existing assemblies that are automatically registered. System assembly is one of them. It contains data mining functions.

These existing assemblies don't have a procedure that lists the functionality provided. However, there are certain DMV queries that can return the same. DMVs are covered later in this chapter.

Additional information

Chapter 14 of the book *Microsoft SQL Server 2008 Analysis Services Unleashed* contains additional information about stored procedures, as well as Chapter 7 of *Professional Microsoft SQL Server Analysis Services 2012 with MDX*. Finally, here's the MSDN reference for stored procedures: <http://tinyurl.com/SSASStoredProcedures>.

If you are interested in extending the functionality of SSAS and MDX by writing .NET stored procedures or user-defined functions, see ADOMD .NET server programming at <http://tinyurl.com/ADOMDNET>.

Executing MDX queries in T-SQL environments

Throughout this book, numerous recipes showed how to create various calculations, either directly in MDX queries or inside the MDX script. Prior to writing and running the queries, you naturally had to establish the connection to your Analysis Services server instance and click on the **New Query** icon, which opened the SQL Server Management Studio's built-in MDX editor. The other option for running those queries, which we didn't show in this book, was to use the other Analysis Services frontend tool that allows writing and executing MDX queries.

To connect to data sources such as Analysis Services, applications use providers. A relational database environment, on the other hand, allows us to use those providers to run distributed queries, also known as pass-through queries. This feature opens the window of possibilities for us. We can combine results from the cube with those in the data warehouse or simply get the flattened result of an MDX query and use it like any other result of T-SQL queries. True, we won't have a nice pane with the cube structure on our left to help us write MDX queries, but nothing stops us from writing them in MDX editor and then copy-pasting the working MDX queries inside the pass-through T-SQL queries.

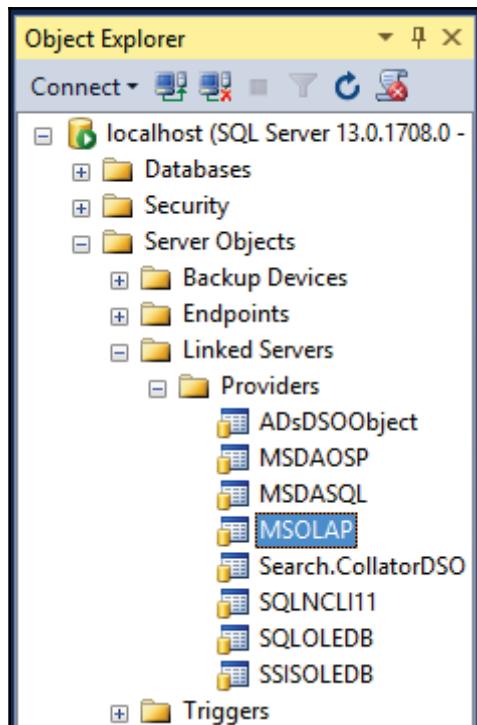

Let's see how it's done.

Getting ready

Start SQL Server Management Studio and connect to your SQL Server 2016 *database engine* instance.

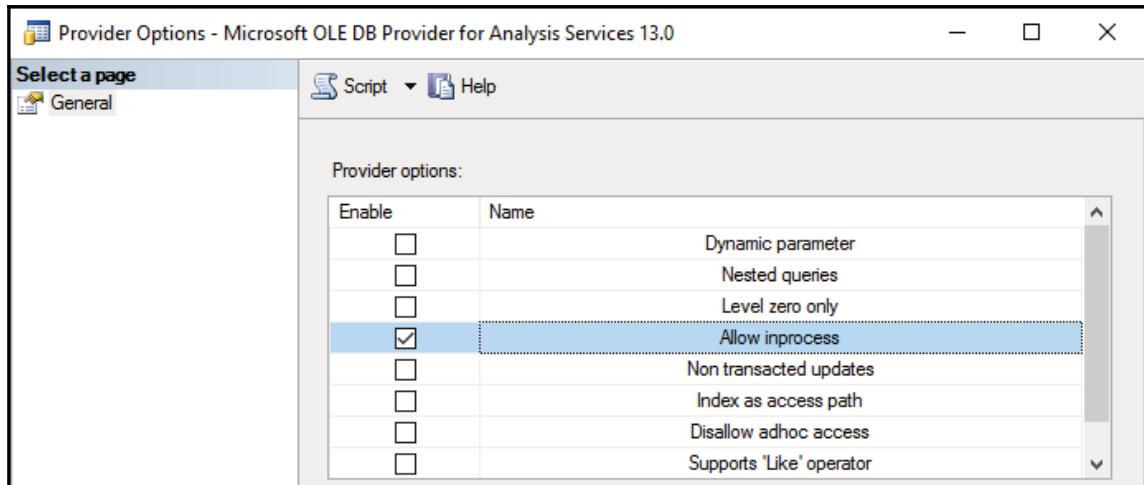

Start a new query by clicking on the **New Query** button.

Expand the **Server Objects** item in the **Object Explorer**. Expand the **Linked Servers** item and then the **Providers** item. Verify that the **MSOLAP** provider is there:

It should be there if you have installed at least the client connectivity for Analysis Services on your computer. If not, then you need to install it from the Microsoft® SQL Server® 2016 Feature Pack found at <http://tinyurl.com/OLEDBproviderSSAS2016>. Look for the OLE DB provider for SSAS there and choose the version of the provider (32-bit or 64-bit) that matches your computer's OS.

Next, double-click on the **MSOLAP** provider and make sure that the **Allow inprocess** option is checked. Optionally check the **Dynamic parameter** option, and close the window.

Now you're ready to query your SSAS servers.

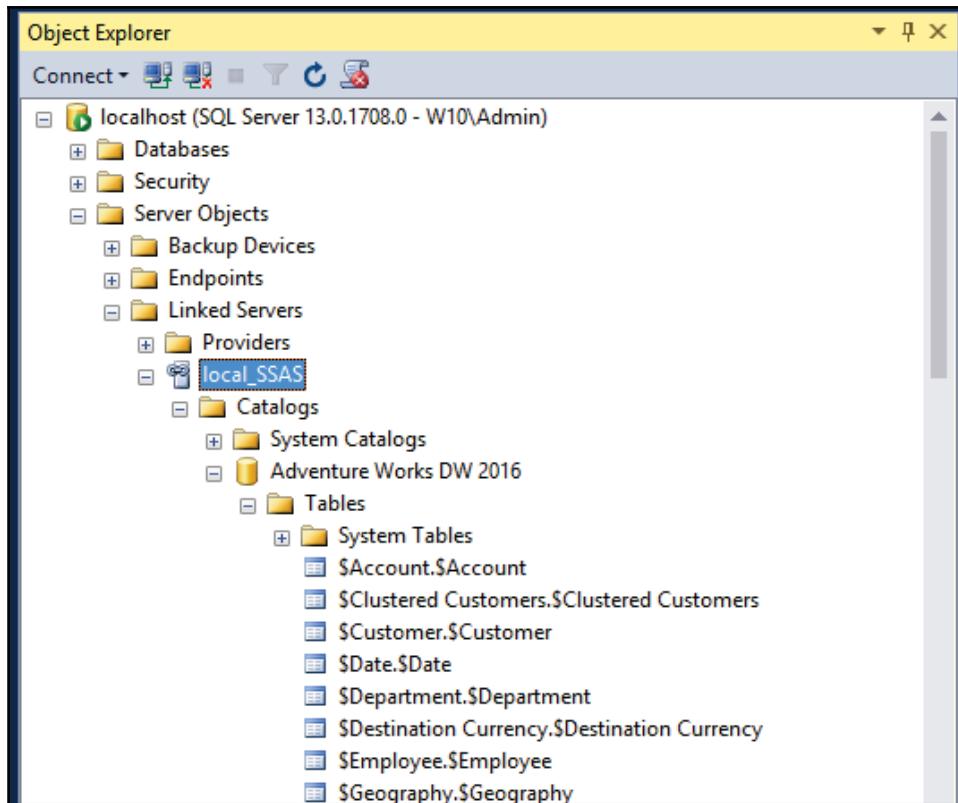

How to do it...

Follow these steps to perform a SQL Server distributed query with your SSAS instance:

1. Register your SSAS instance as a linked server by running the following command:

```
EXEC sp_addlinkedserver
@server='local_SSAS',
@srvproduct='',
@provider='MSOLAP',
@datasrc='.',
@catalog='Adventure Works DW 2016'
```

2. Refresh the **Linked Servers** item in the **Object Explorer** by right-clicking on it and selecting **Refresh**.
3. If everything is successful, you should see your linked server there. You should also be able to navigate to that server and through its tables, as shown in the following screenshot:

4. Run your MDX query as a distributed query:

```
Select * From OpenQuery(local_SSAS,
'
SELECT
    NON EMPTY
        { [Measures].[Sales Amount],
          [Measures].[Gross Profit Margin] } *
        { [Product].[Category].MEMBERS } ON 0,
    NON EMPTY
        { [Product].[Color].MEMBERS } ON 1
FROM
    [Adventure Works]
WHERE
    ( [Date].[Calendar].[Calendar Year].&[2014] )
')
```

5. The result will look like this:

	[Product].[Color].[Color].MEMBER_CAPTION	[Measures].[Sales Amount].[Product].[Category].[All Products]	[Measures].[Sales Amount].[Product].[Category].&[4]
1	NULL	45634.71999999987	30371.35000000024
2	Black	8355.97999999982	2869.179999999971
3	Blue	4879.149999999978	2974.149999999974
4	Multi	4845.349999999849	NULL
5	NA	20708.98000000032	20708.98000000032
6	Red	2554.269999999982	2554.269999999982
7	Silver	1264.77	1264.77
8	White	224.750000000006	NULL
9	Yellow	2861.469999999971	NULL

6. You've successfully executed your MDX query against your SSAS server from the database engine environment, and the server returned the result set in tabular format. The specifics of this output will be discussed in later sections of this recipe.

How it works...

The best way to use an SSAS server in the database engine environment is to register it as a linked server. That can be done either by running the `sp_addlinkedserver` stored procedure, as we did in this example, or by manually registering the server using the **New Linked Server...** option on the **Linked Servers** item. Of course, you should right-click on the item first to see that option.

Registration is a one-time process; it requires the following information:

- The name for the linked server—the way it will be referred to later in the code (here we've named it `local_SSAS`)
- The provider for the server (in this case, it's always the `MSOLAP` provider)
- The SSAS server and the instance (here we've used the local server with the default instance, which can be specified as `(dot)`, `localhost`, `local`, `(local)`, or simply the name of the computer)
- The SSAS database we want to connect to (here, we use the `Adventure Works DW 2016` database, the one we've used throughout this book)

If you enter the information correctly and have the correct **MSOLAP** provider on your computer, then you should be able to see and browse the new linked server. The idea of browsing is merely a test to see whether everything works as expected with the registered linked server.

The MDX that goes into the `OpenQuery` command should be created and tested in a separate query, the one that connects to the SSAS instance, not the relational database instance. The MDX should then be copy-pasted as the second argument of the `OpenQuery` command. To keep the recipe short, we skipped that part and wrote the MDX query directly.

The result of the `OpenQuery` over MSOLAP provider is a bit different from the result returned by the same query executed against the SSAS instance directly. The `All` member is specified only for hierarchies on columns (see the second column in the previous screenshot; that's the `All Products` member of the `Category` hierarchy). In rows, it is returned as a `NULL` value (see the first column in the previous screenshot; that's the `All Products` member of the `Color` hierarchy).

Next, notice that values are flattened to fit the relational form. The columns are a combination (a tuple) of a measure and a dimension. With respect to that, here are some optimization tips.

Try to put the measures on columns and everything else on rows, just like Reporting Services expects it when it uses SSAS as a data source. In this example, we've deliberately made a bad type of query to show you what happens if you put more hierarchies on columns (notice the names of the columns, such as `[Measures].[Sales Amount].[Product].[Category].[All Products]`).

Formats for numeric values are not preserved, but you can always convert column values to database types that suit you. Naturally, you would do that in the outer T-SQL query, not in the inner MDX query.

What's important is that you could get the data from your cube in another environment. In case you need to bring the data back to, let's say Data Warehouse, now you know you can do it.

There's more...

If you don't want to register a linked server, you must configure some of the server options to be able to query the SSAS instance. This can be done either visually by changing some of the server and provider options, or by using the script. We'll show both options, in that order.

Right-click on the server in the **Object Explorer** pane, and then choose **Facets**. In the **Facet** dropdown, select the last item, **Surface Area Configuration**. Then change the first property, **AdHocRemoteQueriesEnabled**, to **True**. This enables the SQL Server to run distributed queries without a linked server.

Close the window using the **OK** button.

The visual option presented earlier is relatively easy to remember. For those of you who need or prefer the script version, here's the alternative:

```
USE [master]
GO
sp_configure 'Show Advanced Options', 1
GO
RECONFIGURE WITH OverRide
GO
sp_configure 'Ad Hoc Distributed Queries', 1
GO
RECONFIGURE WITH OverRide
GO
EXEC master.dbo.sp_MSset_oledb_prop
    'MSOLAP',
    'AllowInProcess', 1
GO
EXEC master.dbo.sp_MSset_oledb_prop
    'MSOLAP',
    'DynamicParameters', 1
GO
```

Now you can query your SSAS instance using the **OpenRowset** syntax:

```
Select * From OpenRowset('MSOLAP',
    'Data Source=.;Initial Catalog=Adventure Works DW 2016;',
    'SELECT [Measures].DefaultMember ON 0
        FROM [Adventure Works]')
```

Additional information

Here are useful links regarding the OpenQuery and OpenRowset commands, linked servers, and other terms mentioned inside this recipe:

- Accessing external data: Available at <http://tinyurl.com/ExternalData>
- Adding a linked server: Available at <http://tinyurl.com/sp-addlinkedserver>
- Linked server properties: Available at <http://tinyurl.com/LinkedServerProperties>
- OpenQuery: Available at <http://tinyurl.com/OpenQueryTSQL>
- OpenRowset: Available at <http://tinyurl.com/OpenRowsetTSQL>
- Ad hoc distributed queries: Available at <http://tinyurl.com/DistributedQueryOptions>

Useful tips

Removing a linked server is easy. Just right-click on that linked server in the **Object Explorer** and choose the **Delete** option. Confirm and you're done.

You can also script the linked server for future use by using the **Script Linked Server as...** option. This feature is available in the context menu (by right-clicking on the linked server).

Accessing Analysis Services 2000 from a 64-bit environment

The technique presented in this recipe can also be useful to make the SSAS 2000 server accessible from a 64-bit server. The 32-bit SQL Server 2005 or later can be used as a gateway by using a linked server.

Troubleshooting the linked server

If you have trouble accessing an SSAS linked server, here are the things that you should check:

- Are you using the correct MSOLAP provider to connect to your server?
- Have you entered the correct SSAS instance?
- Have you used the correct database?
- Do you have all the necessary server options enabled for the type of the query you're trying to make?
- Is the SSAS database processed?
- Do you have permissions to connect and use that database?

You can eliminate these questions one by one by verifying them, that is, using SSMS to connect to the SSAS database, opening configuration dialogs, and so on. This way you will narrow down the potential causes and soon be able to focus on solving the rest of the items.

- The *Using SSAS Dynamic Management Views (DMVs) to fast-document a cube* recipe for fast documenting of a cube is related to this recipe because it shows the opposite-how to run SQL-like queries in an MDX query environment

Using SSAS Dynamic Management Views (DMVs) to fast-document a cube

Dynamic Management Views (DMV) are Analysis Services schema rowsets (XML/A metadata) exposed as tables, which can be queried with SELECT statements.

DMVs expose information about local Analysis Services server metadata and server operations. For most DMV queries, you use a SELECT statement and the \$System schema with an XML/A schema rowset:

```
SELECT * FROM $System.<schemaRowset>
```

The query engine for DMVs is the Data Mining parser. The DMV query syntax is based on the SELECT (DMX) statement. To execute DMV queries, you can use any client application that supports MDX or DMX (Data Mining) queries, including SQL Server Management Studio, a Reporting Services Report, or a Performance Point Dashboard. In this recipe and the next recipe, we use the MDX query window in SSMS.

It is also worth mentioning that although DMV query syntax is based on a SQL SELECT statement, it does not support the full syntax of a SELECT statement. Notably, JOIN, GROUP BY, LIKE, CAST, and CONVERT are not supported.

There are four collections in DMVs and they are: DBSCHEMA, MDSchema (Multi-dimensional), DISCOVER, and DMSchema (Data Mining).

The first collection of DMVs is the DBSCHEMA collection, which consists of four DMVs. Its purpose is to provide various metadata about tables and other relational objects that SSAS databases are built from. For example, DBSCHEMA_COLUMNS can provide a list of columns in dimension tables in DSV.

The second collection is the MDSchema collection. This collection exposes various metadata about objects in SSAS databases. For example, we can find information about the cubes, dimensions, measures, levels, members, actions, and so on defined in the current database.

The third collection is the DMSchema collection, which is dedicated to data mining. For example, the DMSchema_MINING_STRUCTURES schema rowset can provide you a list of all mining structures in the current SSAS database.

Lastly, the biggest collection is the DISCOVER collection. It tells us how many active connections the server has, which queries are running now, which sessions are active, and various pieces of information about the memory, CPU usage, and other server resources.

DMVs can be very useful for documenting SSAS databases, monitoring usage and activity, being the source for operational monitoring reports, and other purposes. In short, they are important enough to be covered in a recipe. In fact, we dedicate two recipes to DMVs. This recipe shows how to use them to document the cube. The next one deals with monitoring the activity and usage.

Getting ready

Start SQL Server Management Studio and connect to your SSAS 2016 instance. Click on the **New Query** button and check that the target database is Adventure Works DW 2016.

As we mentioned in the introduction, we can use either the MDX query window or the DMX query window in SSMS to execute DMV queries, but we choose to use the MDX query window. This is the query window where you normally write MDX queries. The SSAS server recognizes the DMV queries and will redirect them to the Data Mining parser, which is the query engine for DMVs.

Here's the first query we're going to run:

```
select * from $system.Discover_Schema_Rowsets
```

This query returns all available schema rowsets. It can be a good starting point to use other DMVs because it lists all of them and their restrictions.

SchemaName	SchemaGuid	Restrictions	Description	RestrictionsMask
DBSCHEMA_CATALOGS	c8b52211-5cf3-11ce-adef5-00aa0044773d	+ Restrictions	1	
DBSCHEMA_TABLES	c8b52229-5cf3-11ce-adef5-00aa0044773d	+ Restrictions	31

MDSHEMA_SETS	a07cc0d-8148-11d0-87bb-00c04fc33942	+ Restrictions	255	
DISCOVER_INSTANCES	20518699-2474-4c15-9885-0e947ec7a7e3	+ Restrictions	1	
MDSHEMA_KPIS	2ae44109-ed3d-4842-b16f-b694d1cb0e3f	+ Restrictions	63	
MDSHEMA_MEASUREGROUPS	e1625ebfa9642fd-bea6-db90adaf96b	+ Restrictions	15	
MDSHEMA_MEASUREGROUP_DIMENSIONS	a07cc033-8148-11d0-87bb-00c04fc33942	+ Restrictions	63	
MDSHEMA_INPUT_DATASOURCES	a07cc032-8148-11d0-87bb-00c04fc33942	+ Restrictions	15	
DMSHEMA_MINING_SERVICES	3add8a95-d8b9-11d2-8d2a-00e029154fe	+ Restrictions	3	

In this recipe, we're going to use the **MDSHEMA** collection, starting with the **MDSHEMA_LEVELS** DMVs, which list all the attributes in a cube.

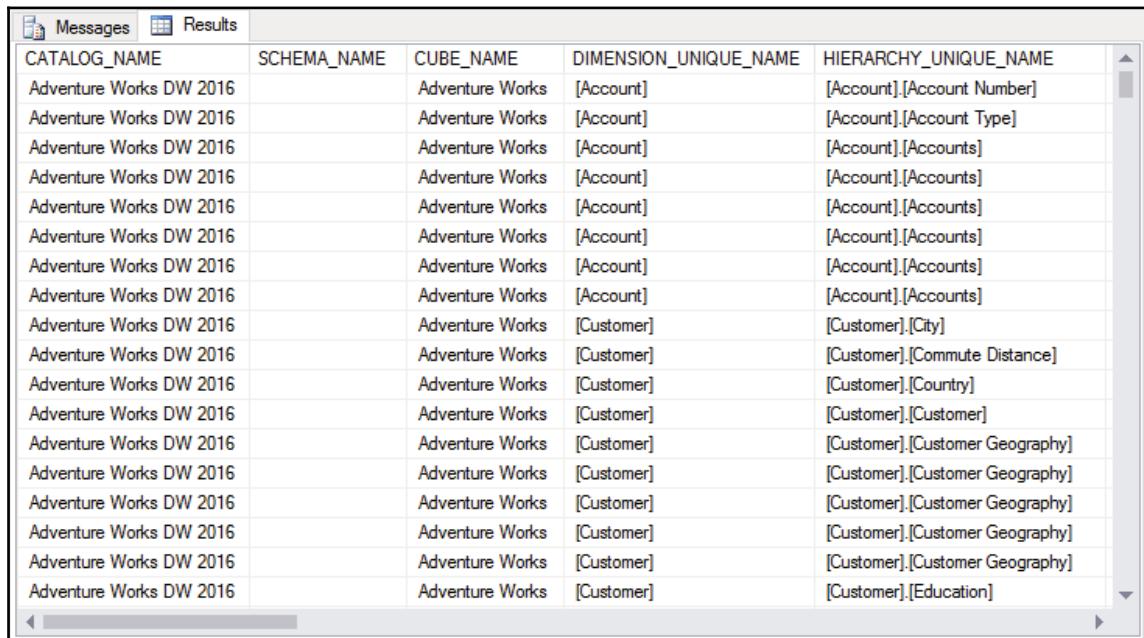

How to do it...

Follow these steps to get detailed information about attributes in an SSAS database, cube, or dimension depending upon how you set the restrictions:

1. In the MDX query window, execute the following query:

```
SELECT
    *
FROM
    $system.MDSHEMA_LEVELS
WHERE
    [CATALOG_NAME] = 'Adventure Works DW 2016'
    AND LEFT(CUBE_NAME, 1) <> '$' -- avoid dimension cubes
    AND [LEVEL_TYPE] <> 1 -- avoid root levels
    AND LEVEL_IS_VISIBLE -- avoid hidden levels
```

2. A table with many columns and rows is returned. This represents detailed information about the attributes visible in the **Adventure Works DW 2016** database and its cube and dimensions:

The screenshot shows an MDX query results window with two tabs: 'Messages' and 'Results'. The 'Results' tab is selected and displays a table with five columns: CATALOG_NAME, SCHEMA_NAME, CUBE_NAME, DIMENSION_UNIQUE_NAME, and HIERARCHY_UNIQUE_NAME. The table contains 20 rows, each representing an attribute from the Adventure Works DW 2016 database. The data is as follows:

CATALOG_NAME	SCHEMA_NAME	CUBE_NAME	DIMENSION_UNIQUE_NAME	HIERARCHY_UNIQUE_NAME
Adventure Works DW 2016		Adventure Works	[Account]	[Account].[Account Number]
Adventure Works DW 2016		Adventure Works	[Account]	[Account].[Account Type]
Adventure Works DW 2016		Adventure Works	[Account]	[Account].[Accounts]
Adventure Works DW 2016		Adventure Works	[Account]	[Account].[Accounts]
Adventure Works DW 2016		Adventure Works	[Account]	[Account].[Accounts]
Adventure Works DW 2016		Adventure Works	[Account]	[Account].[Accounts]
Adventure Works DW 2016		Adventure Works	[Account]	[Account].[Accounts]
Adventure Works DW 2016		Adventure Works	[Customer]	[Customer].[City]
Adventure Works DW 2016		Adventure Works	[Customer]	[Customer].[Commute Distance]
Adventure Works DW 2016		Adventure Works	[Customer]	[Customer].[Country]
Adventure Works DW 2016		Adventure Works	[Customer]	[Customer].[Customer]
Adventure Works DW 2016		Adventure Works	[Customer]	[Customer].[Customer Geography]
Adventure Works DW 2016		Adventure Works	[Customer]	[Customer].[Customer Geography]
Adventure Works DW 2016		Adventure Works	[Customer]	[Customer].[Customer Geography]
Adventure Works DW 2016		Adventure Works	[Customer]	[Customer].[Customer Geography]
Adventure Works DW 2016		Adventure Works	[Customer]	[Customer].[Education]

3. Scroll the table in both directions to familiarize yourself with the contents of that table.
4. Right-click on the result, **Select All**, copy the content, and paste it somewhere where you will assemble this data into documentation.
5. Repeat the process with the other **MDSHEMA** DMVs. To remove the conditions that don't fit, run the query with no restrictions and then add those restrictions that you think will help you get the result you need. Skip **MEMBERS DMV**; it might be huge and it's not like you will need it in the documentation.

How it works...

Running a query with a DMV inside it is simple. The biggest challenge is to find out, or remember, which schema rowsets can be used. The good thing is that you need to memorize only a single DMV; the `$system.Discover_Schema_Rowsets` DMV.

The `$system` schema is common to all DMVs, so that shouldn't be hard to remember. The `Discover_Schema_Rowsets` is the phrase we need to memorize to use DMVs without the documentation. Running this DMV returns the names and restrictions for all other DMVs.

As we said in the introduction, there are four collections of DMVs. In this recipe, we've used **MDSHEMA**, which is a shortcut for multidimensional schema. This collection tells us everything about SSAS databases and their objects. By repeatedly collecting results from DMVs in that collection, which are important to us, we can assemble the documentation quickly and relatively easily.

Conditions applied to a particular DMV serve the purpose of limiting the result to only those rows that we need. For example, in this recipe we've deliberately removed dimension cubes, cubes starting with the `$` prefix. We've also focused on a single database and excluded all root and hidden levels so that our documentation becomes smaller and less distracting. It is up to you whether you'll use the same conditions or not.

Conditions for other DMVs can be set after each of them is run without any conditions and by analyzing which of them can be applied in a particular case.

The good thing is that once you make a set of **MDSHEMA** DMV queries that suits your needs, you can use them on any SSAS database. In other words, it's all about preparation. This recipe showed you how to do this.

There's more...

You can execute queries with DMVs as distributed queries (see previous recipe). All you should do is either register a linked server or enable the **Ad Hoc Distributed Queries** option using the T-SQL script presented in the previous recipe, and then run an `OpenQuery` or `OpenRowset` query.

Here's the query that uses the linked server defined in the previous recipe and returns lots of information about dimensions in the Adventure Works DW 2012 database:

```
Select * From OpenQuery(local_SSAS,
'
SELECT *
FROM
$system.mdschema_DIMENSIONS
WHERE
[CATALOG_NAME] = ''Adventure Works DW 2016''
AND LEFT(CUBE_NAME, 1) <> '$' -- avoid dimension cubes
AND DIMENSION_IS_VISIBLE -- avoid hidden dimensions
AND DIMENSION_TYPE <> 2 -- avoid measures
')
```

Notice that you should use double quotes around the database name and the \$ sign because the MDX query is one big string now. We don't want to terminate it; we want to emphasize that there's a quote inside and the way we do it is by using another quote next to it.

This is what you get when you run the query:

	CATALOG_NAME	SCHEMA_NAME	CUBE_NAME	DIMENSION_NAME	DIMENSION_UNIQUE_NAME
1	Adventure Works DW 2016	NULL	Adventure Works	Account	[Account]
2	Adventure Works DW 2016	NULL	Adventure Works	Customer	[Customer]
3	Adventure Works DW 2016	NULL	Adventure Works	Date	[Date]
4	Adventure Works DW 2016	NULL	Adventure Works	Delivery Date	[Delivery Date]
5	Adventure Works DW 2016	NULL	Adventure Works	Department	[Department]
6	Adventure Works DW 2016	NULL	Adventure Works	Destination Currency	[Destination Currency]
7	Adventure Works DW 2016	NULL	Adventure Works	Employee	[Employee]
8	Adventure Works DW 2016	NULL	Adventure Works	Geography	[Geography]
9	Adventure Works DW 2016	NULL	Adventure Works	Internet Sales Order Details	[Internet Sales Order Details]
10	Adventure Works DW 2016	NULL	Adventure Works	Organization	[Organization]
11	Adventure Works DW 2016	NULL	Adventure Works	Product	[Product]
12	Adventure Works DW 2016	NULL	Adventure Works	Promotion	[Promotion]
13	Adventure Works DW 2016	NULL	Adventure Works	Reseller	[Reseller]
14	Adventure Works DW 2016	NULL	Adventure Works	Reseller Sales Order Details	[Reseller Sales Order Details]
15	Adventure Works DW 2016	NULL	Adventure Works	Sales Channel	[Sales Channel]
16	Adventure Works DW 2016	NULL	Adventure Works	Sales Reason	[Sales Reason]
17	Adventure Works DW 2016	NULL	Adventure Works	Sales Summary Order Details	[Sales Summary Order Details]
18	Adventure Works DW 2016	NULL	Adventure Works	Sales Territory	[Sales Territory]

Again, only a small portion of information is visible in this screenshot. You will be able to scroll in both directions and see what else is available.

Tips and tricks

When you run the `$system.DSDiscover_Schema_Rowsets` DMV, you can expand the **Restrictions** item for a particular DMV to find out which columns can be used to set the filter for that particular DMV.

You can also use column names instead of * to avoid empty columns.

You can't convert data types directly in DMVs, but you can do that in the outer part of the OpenQuery query. Remember that for certain joins, you will need to convert the `ntext` data type to `nvarchar(max)` data type.

You can join multiple DMVs using the OpenQuery statement and create interesting reports.

As we mentioned in the introduction, DMV query syntax does not support JOIN, GROUP BY, LIKE, CAST, and CONVERT. However, we can bypass this inconvenience by running the DMV queries as distributed queries in the T-SQL environment.

Warning!

The connection determines the context!

In other words, when you connect to, let's say, the Adventure Works DW 2016 Standard Edition database, the DMVs will return metadata about that database only.

Always make sure you are connected to the right database when you query DMVs.

If you run into a permission issue when querying DMVs, you need to make sure that you have system administrator permissions on the SSAS instance.

More information

- The MSDN library contains more information about DMVs and the columns they return: <http://tinyurl.com/MSDN-DMVs>
- Vincent Rainardi has a good overview of DMVs here: <http://tinyurl.com/VinentDMVs>
- Vidas Matelis aggregates DMV-based articles on his SSAS-Info portal here: <http://www.ssas-info.com/tags/68-dmv>

Finally, there are a few interesting DMV-related community samples at Codeplex (see everything related to monitoring or DMVs):

<http://tinyurl.com/SSASCodePlex>

Using SSAS Dynamic Management Views (DMVs) to monitor activity and usage

The previous recipe explained what DMVs are and illustrated how they can be used to get information about SSAS objects using the **MDSCHHEMA** collection of DMVs.

In this recipe, we're shifting focus to another collection of DMVs, the **DISCOVER** collection. This is the largest collection of DMVs. DMVs in this collection can be used to monitor the usage of the cube in all its aspects.

Getting ready

Start **SQL Server Management Studio** and connect to your SSAS 2016 instance. Click on the **New Query** button and check that the target database is **Adventure Works DW 2016**.

As explained in the previous recipe, the MDX query window supports DMV queries. Let's run a query to verify that:

```
select * from $system.Discover_Schema_Rowsets
```

When run, this query returns all available schema rowsets. As mentioned in the previous recipe, this can be a good starting point for using other DMVs because it lists them and their restrictions.

Now, scroll through that list and notice the names of the DMVs from the **DISCOVER** collection. As a matter of fact, why not show another query that we can write to isolate DMVs in that schema:

```
select * from $system.Discover_Schema_Rowsets
where left(SchemaName, 8) = 'DISCOVER'
order by SchemaName
```

The previous query lists all DMVs in that schema. The list is big, so only a portion of it is shown in the next screenshot, but it should be enough to give you an idea of what you can get using the DMVs in this collection:

SchemaName
DISCOVER_CALC_DEPENDENCY
DISCOVER_COMMAND_OBJECTS
DISCOVER_COMMANDS
DISCOVER_CONNECTIONS
DISCOVER_CSDL_METADATA
DISCOVER_DATASOURCES
DISCOVER_DB_CONNECTIONS
DISCOVER_DIMENSION_STAT
DISCOVER_ENUMERATORS
DISCOVER_INSTANCES
DISCOVER_JOBS
DISCOVER_KEYWORDS
DISCOVER_LITERAL
DISCOVER_LOCATIONS
DISCOVER_LOCKS
DISCOVER_MASTER_KEY
DISCOVER_MEMORYGRANT
DISCOVER_MEMORYUSAGE
DISCOVER_OBJECT_ACTIVITY
DISCOVER_OBJECT_MEMORY_USAGE
DISCOVER_PARTITION_DIMENSION_STAT
DISCOVER_PARTITION_STAT
DISCOVER_PERFORMANCE_COUNTERS

OK, let's see some of the most interesting ones in action.

How to do it...

Follow these steps to see information about the activity on your SSAS server. The queries will return unique results based on your activity on the server. Therefore, only the queries are presented; there are no screenshots:

1. Execute this query to see the list of connections:

```
select * from $system.DISCOVER_CONNECTIONS
```

2. Execute the following query to see the list of sessions. You can additionally limit it using a particular connection:

```
select * from $system.DISCOVER_SESSIONS
```

3. Execute this to see the list of commands. You can additionally limit the list using a particular session:

```
select * from $system.DISCOVER_COMMANDS
```

4. Execute the following query to see the accumulated results of users' activity since the last restart of the service. Here, for example, you can order the query to see which aggregations and objects are hit or missed the most, as well as the CPU activity spent on each object so far (since the restart of the SSAS service):

```
select * from $system.DISCOVER_OBJECT_ACTIVITY
```

5. Execute the following query to see the detailed list of memory usage per object:

```
select * from $system.DISCOVER_MEMORYUSAGE
```

6. Execute this query to see the spread of shrinkable and non-shrinkable memory usage per object:

```
select * from $system.DISCOVER_OBJECT_MEMORY_USAGE
```

7. Explore the other DMVs in the **DISCOVER** collection, to see what they return, and if you can benefit from that information in the monitoring solution you plan to build. If you encounter an error, skip that DMV. The explanation will be covered in later sections of this recipe.

How it works...

Querying the **DISCOVER** collection in DMVs is easy when you know what they represent and how are they related. Until then, you might be a little lost.

Unlike the **MDSHEMA** DMVs, which follow the natural path of objects and their descending objects (for example, the database, dimensions and cubes, hierarchies of dimensions, levels of hierarchies, and so on), here we have several entry points and each entry point leads to more detailed DMVs.

We started the example with the list of connections returned by the **DISCOVER_CONNECTIONS** DMV. Connections have sessions; therefore, the next DMV we covered was the **DISCOVER_SESSIONS** DMV. Naturally, we can create a query that joins those two results into one if we want to, and this can be done using the `OpenQuery` statement (joins will be covered in later sections of this recipe).

The **DISCOVER_COMMANDS** DMV is here to give us more details about the queries running in each session.

The **DISCOVER_OBJECT_ACTIVITY** DMV is great for performance tuning your cube. It includes information about aggregation hits, aggregation misses, object hits and misses, CPU time spent so far (from the restart of SSAS service) on a particular object, and so on. Monitoring this DMV on a regular basis can give you valuable information, such as whether there's a place for improving your cube by building additional aggregations or by warming up the cache.

The last two DMVs covered in this recipe were DMVs that inform us about the memory usage in case we want to fine-tune SSAS settings regarding memory consumption and its limits.

There's more...

Some DMVs require restrictions. You must use the `SystemRestrictSchema` function to run them. Here is the list of some DMVs that require restrictions and that are part of the **DISCOVER** collection:

- \$system.DISCOVER_DIMENSION_STAT
- \$system.DISCOVER_INSTANCES

- \$system.DISCOVER_PARTITION_DIMENSION_STAT
- \$system.DISCOVER_PARTITION_STAT
- \$system.DISCOVER_PERFORMANCE_COUNTERS
- \$system.DISCOVER_XML_METADATA

Here's the error we get when we run the first DMV in that list:

Executing the query...

Errors from the SQL query module: The **DIMENSION_NAME** restriction is required but is missing from the request. Consider using **SYSTEMRESTRICTSCHEMA** to provide restrictions.

Run complete

The list of parameters for restrictions is visible under the **Restrictions** column, when you run the **DISCOVER_SCHEMA_ROWSETS** DMV, the first one we mentioned in this and the previous recipe. Yes, that's the starting DMV, the one that tells you which DMVs are available in the system.

The usage is as follows:

We need to wrap the DMV and its required parameters inside the **SystemRestrictSchema** function. Here's how:

```
select * from
SystemRestrictSchema(
    $system.DISCOVER_DIMENSION_STAT,
    DATABASE_NAME='Adventure Works DW 2016',
    DIMENSION_NAME='Customer')
order by ATTRIBUTE_NAME
```

This query returns all attributes in the *Customer* dimension, real attributes and properties. Additionally, the cardinality of each attribute is displayed.

You would think that this type of DMV fits better in the **MDSchema**, not the **DISCOVER** schema. There, in **MDSchema**, we have two similar DMVs, but neither of them is the same as this DMV. **MDSchema_LEVELS** returns real attributes and their cardinality (and a bunch of other information), but it doesn't return the properties. On the other hand, they can be returned together with real attributes in another **MDSchema** DMV, the **MDSchema_PROPERTIES** DMV. However, here we don't have any cardinality.

To summarize, some DMVs overlap. Look for the DMV that returns the exact information you need. In case none of them do, see if you can join them, and then take whatever you need.

Speaking of joins, here's how you would do that.

You can execute DMV queries as pass-through queries (see the *Executing MDX queries in T-SQL environments* recipe) from the T-SQL environment. All you have to do is either register a linked server or enable the **Ad Hoc Distributed Queries** option using the T-SQL script shown in that recipe, and then run an `OpenQuery` or `OpenRowset` query.

Here's the query that uses the linked server defined in the recipe *Executing MDX queries in T-SQL environments*. Don't forget to run it in the **Database Engine Query** window, not the **Analysis Services MDX Query** window:

```
Select * from OpenQuery(local_SSAS,
    'select * from $system.DISCOVER_CONNECTIONS') c

inner join OpenQuery(local_SSAS,
    'select * from $system.DISCOVER_SESSIONS') s

    on s.SESSION_CONNECTION_ID = c.CONNECTION_ID
inner join OpenQuery(local_SSAS,
    'select * from $system.DISCOVER_COMMANDS') co

    on co.SESSION_SPID = s.SESSION_SPID
```

The result will be unique to the usage pattern of your cube and will show information about objects that have recently been queried.

- The *Using SSAS Dynamic Management Views (DMVs) to fast-document a cube* recipe is related to this recipe as well as the *Executing MDX queries in T-SQL environments* recipe

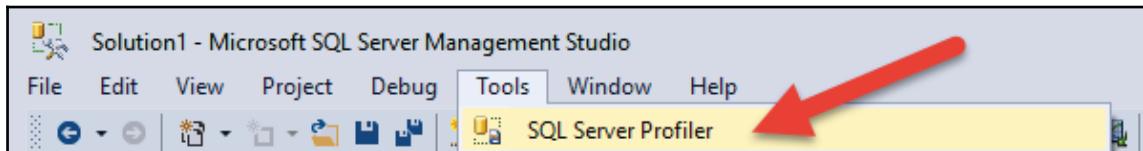

Capturing MDX queries generated by SSAS frontends

Some tools allow you to write your own MDX queries; others generate them for you. If you want to know what these other MDX queries look like, you need to use another tool that will tell you that. One such tool is the **SQL Server Profiler**, which comes as a part of the SQL Server installation. Others might come as add-ins to the application that generates MDX queries.

In this recipe, we're going to show how to capture the MDX query that has been sent by an application to the server using SQL Server Profiler.

Getting ready

In **Microsoft SQL Server Management Studio** for SQL Server 2016, **SQL Server Profiler** can be found in the **Tools** menu:

If after starting the Profiler a window appears offering us to select the connection, press *ESC* for now. This time we will start from scratch.

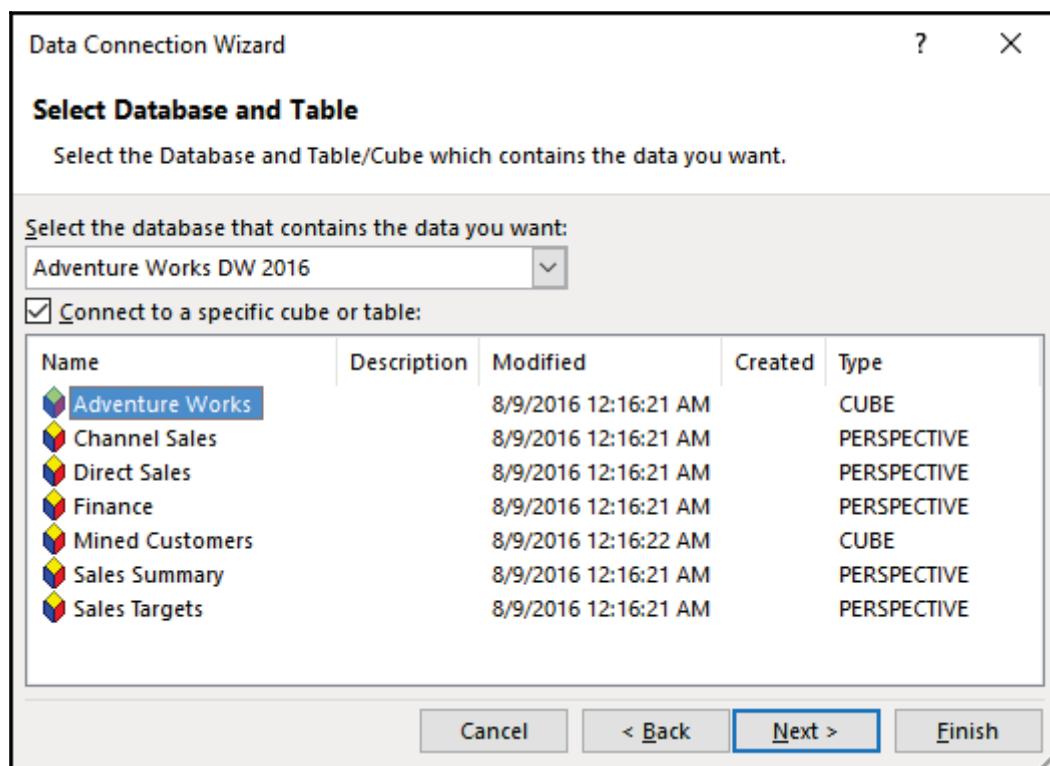

We will start a new template by clicking on the **File** menu, followed by **Templates**, and then choosing the **New Template...** item.

Select **Microsoft SQL Server 2016 Analysis Services** for the **Server Type**. Provide the name for the template: **MDX queries**. If you rarely perform other activities in the Profiler, you can optionally make this template the default template by selecting the appropriate checkbox in that window.

Next, go to the other tab in this window, the **Events Selection** tab. Expand **Queries Events** and select all items there. If you want to know more internal details about how the query performs, select items in the **Query Processing** category. See *Using SQL Profiler* in the MSDN library by clicking on the **Help** button if you need additional information.

Finally click on the **Save** button. The template is now saved and ready to be used every time we need it in the future.

Before we can see how it would go, we should prepare something else. We need to simulate a working environment, where users are browsing the cubes, and analyze the data in their frontends, which in turn generate MDX queries we can capture. Since we're not in this situation, we're going to simulate it using the **Excel PivotTable**. Start Excel, click on the **Data** menu, find **From Other Sources** on the ribbon and choose **From Analysis Services**. In **Data Connection Wizard**, provide server name and choose **Use Windows Authentication** as log-on credentials. Next, choose the **Adventure Works DW 2016** database and the **Adventure Works** cube.

The next step is to save the data connection file and click on **Finish**. In the next **Import Data** window, make sure that you choose **PivotTable Report** to view the cube data.

Now we're ready to go.

How to do it...

Follow these steps to capture the MDX query sent to a cube on an Analysis Services instance:

1. In SQL Server Profiler, click on the **File** menu and then choose the **New Trace...** item.
2. Verify that the server type is set to **Analysis Services** (or change it if it's not) and verify the name of the server you're connecting to. Then click on the **Connect** button.
3. In the **Trace Properties** window select your MDX queries template and name the trace appropriately, for example, **Trace MDX 1**.
4. Optionally, you can choose to save the trace results in a file or a table by selecting the appropriate option in the **General** tab of this window. Pay attention to performance when you write log information into a table.
5. In the **Events Selection** tab, you can change the events you're planning to track by selecting the **Show all events** option (and the **Show all columns** option, for more customization of this trace). We are going to leave it as it is this time and then click on **Run**.
6. Maximize the inner window to see the results better.
7. If you're alone on this server, nothing will happen. That's why we're going to use Excel and its **PivotTable Report** to simulate users querying the cube. If on the other hand, you're tracking an active server, you'll see events appearing in your running trace.
8. Expand the **Measures** item in Excel's **PivotTable Field List** pane (if not already expanded) and drag the **Sales Amount** measure, found under the **Sales Summary** folder, and drop it in the **Values** area.

9. There are new events captured in your trace, as displayed in this screenshot. It looks like there is one query issued:

The screenshot shows the SQL Server Profiler interface with a single trace event listed in the results grid. The event is of type 'Query Begin' and occurred in the 'Adventure Works DW 2016' database. The corresponding 'TextData' shows a simple SELECT statement:

```
SELECT FROM [Adventure Works] WHERE...
```

Below the results grid, a status bar indicates 'Trace is running.' and provides navigation information: 'Ln 2, Col 7' and 'Rows: 2'. A 'Connections: 1' message is also visible.

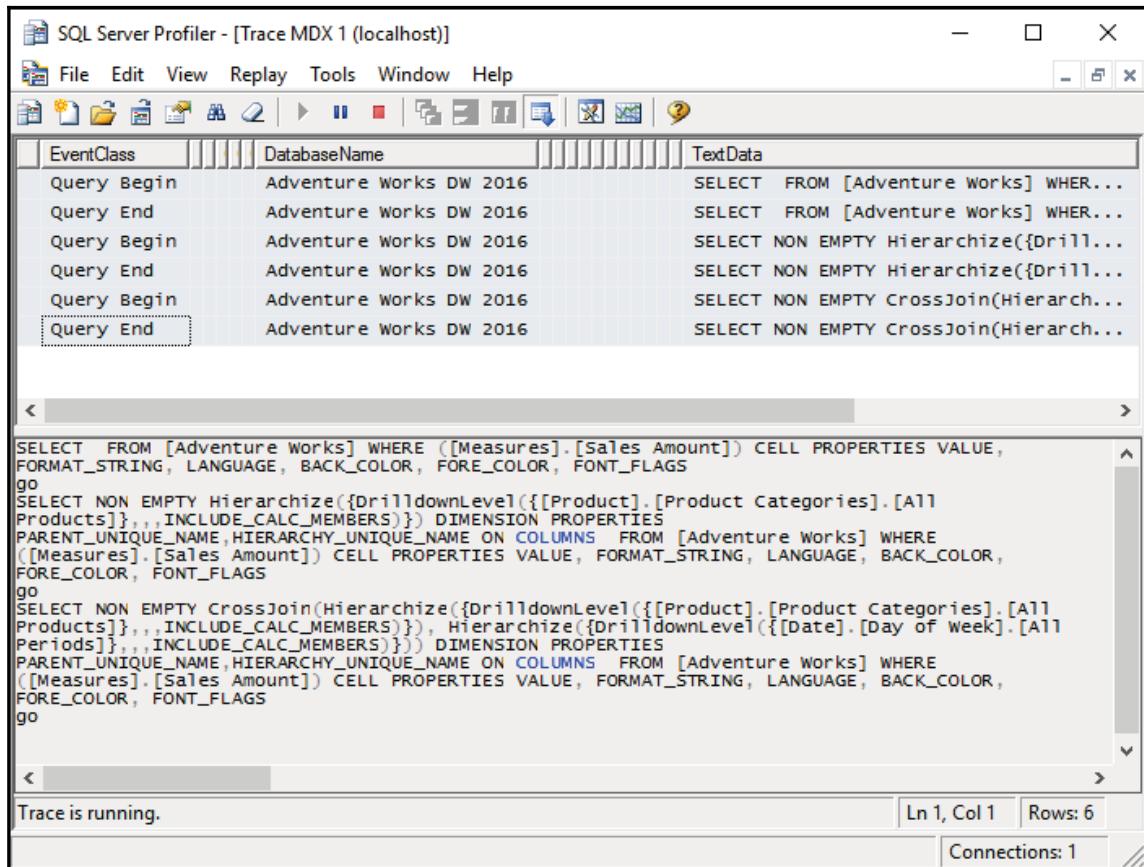

10. Expand the **Product** dimension in Excel. Drag and drop the **Product Categories** user hierarchy on the Row Labels area.
 11. There are new trace events. If you want to see them together, select those rows like the following screenshot shows:

The screenshot shows the SQL Server Profiler interface with four trace events listed in the results grid. The events are of types 'Query Begin' and 'Query End', all occurring in the 'Adventure Works DW 2016' database. The corresponding 'TextData' shows complex MDX queries related to the Product dimension:

```
SELECT FROM [Adventure Works] WHERE ([Measures].[Sales Amount]) CELL PROPERTIES VALUE, FORMAT_STRING, LANGUAGE, BACK_COLOR, FORE_COLOR, FONT_FLAGS
go
SELECT NON EMPTY Hierarchy([Product].[Product Categories].[All Products]), INCLUDE_CALC_MEMBERS) DIMENSION PROPERTIES PARENT_UNIQUE_NAME, HIERARCHY_UNIQUE_NAME ON COLUMNS FROM [Adventure Works] WHERE ([Measures].[Sales Amount]) CELL PROPERTIES VALUE, FORMAT_STRING, LANGUAGE, BACK_COLOR, FORE_COLOR, FONT_FLAGS
go
```

Below the results grid, a status bar indicates 'Trace is running.' and provides navigation information: 'Ln 1, Col 1' and 'Rows: 4'. A 'Connections: 1' message is also visible.

12. Now, expand the Date dimension and drag and drop the Day of Week attribute on the **Row Labels** area again.
13. We have six trace events altogether which means three queries:

The screenshot shows the SQL Server Profiler interface with a trace named "Trace MDX 1 (localhost)". The "Events" tab is selected, displaying a list of captured events. The columns are "EventClass", "DatabaseName", and "TextData". The "TextData" column contains six captured MDX queries. Below the table, the captured queries are displayed in the "Text" pane. The queries are as follows:

```

SELECT FROM [Adventure Works] WHERE ([Measures].[Sales Amount]) CELL PROPERTIES VALUE,
FORMAT_STRING, LANGUAGE, BACK_COLOR, FORE_COLOR, FONT_FLAGS
go
SELECT NON EMPTY Hierarchize({DrilldownLevel({[Product].[Product Categories].[All
Products]}},INCLUDE_CALC_MEMBERS)}) DIMENSION PROPERTIES
PARENT_UNIQUE_NAME,HIERARCHY_UNIQUE_NAME ON COLUMNS FROM [Adventure Works] WHERE
([Measures].[Sales Amount]) CELL PROPERTIES VALUE, FORMAT_STRING, LANGUAGE, BACK_COLOR,
FORE_COLOR, FONT_FLAGS
go
SELECT NON EMPTY CrossJoin(Hierarchize({DrilldownLevel({[Product].[Product Categories].[All
Products]}},INCLUDE_CALC_MEMBERS)}, Hierarchize({DrilldownLevel({[Date].[Day of Week].[All
Periods]}},INCLUDE_CALC_MEMBERS)})) DIMENSION PROPERTIES
PARENT_UNIQUE_NAME,HIERARCHY_UNIQUE_NAME ON COLUMNS FROM [Adventure Works] WHERE
([Measures].[Sales Amount]) CELL PROPERTIES VALUE, FORMAT_STRING, LANGUAGE, BACK_COLOR,
FORE_COLOR, FONT_FLAGS
go

```

The status bar at the bottom indicates "Trace is running.", "Ln 1, Col 1", "Rows: 6", and "Connections: 1".

14. The process can continue as long as you want or need, but this is where we'll stop with the trace. Click on the **Stop Selected Trace** button in the toolbar.
15. Congratulations! You've managed to capture all MDX queries sent to your server in a given time period.
16. Finally, save the trace if you want to preserve its contents. Otherwise, simply close the trace and the Profiler after it.

How it works...

The Profiler is a tool that captures a lot of events regarding the SQL Server. In this case, we were interested in the SSAS-related events, more precisely, the MDX query events.

There are two events in that group of events: `Query Begin` and `Query End` events. We tracked them both because it allowed us to see the start, and the duration of captured queries. In practice, you can choose to track only the `Query End` event, the one which has the information about the duration of queries.

Multi-selection of events allowed us to merge queries in one pane.

As seen in this example, one user action can lead to one or many MDX queries generated in the background by an application. This can cause problems to special context-sensitive calculations presented in Chapter 8, *When MDX is Not Enough*, because those calculations depend on each report being a single MDX statement. In fact, this is how you would debug what's wrong with your calculations – you could see what an application did with them and how they were used in the query. In short, it benefits knowing that you can capture and later analyze any query that's in the background of an analytical report created in an application.

There's more...

There is much more information you can capture regarding MDX queries, but this goes out of the scope of this book. For more information, see the book *Expert Cube Development with SSAS Multidimensional Models* or SQLCAT's white paper *Identifying and Resolving MDX Query Performance Bottlenecks in SQL Server 2005 Analysis Services*.

Alternative solution

There are add-ins for some SSAS frontends which enable you to see the MDX right inside the add-in, without the need to use Profiler. One such popular add-in is the Excel add-in which can be downloaded from here: <http://tinyurl.com/PivotTableExtensions>.

The site also contains instructions for its usage. Other add-ins might be available too, so make sure you've searched the Internet and found the one that's right for you.

In Analysis Services 2016, both the Cube Browser in SSMS and SSDT are now replaced by a Query Design Wizard. By toggling between the graphic mode and the design mode, you can see the MDX query.

Tips and tricks

You can create several templates in the Profiler and use each in the appropriate situation. That way you will work faster without having to worry about selecting the right events manually every time.

See also

- The next recipe, *Performing a custom drillthrough*, is related to this recipe

Performing a custom drillthrough

Multidimensional database systems like Analysis Services naturally support the top-down analysis approach. Data can be browsed using multilevel hierarchies, starting from the top level and descending to the levels we need to. This cube data is typically aggregated at different levels.

There is another side to the story. Users occasionally want to see every single detail about an aggregated value represented in a single cell in pivot. This information originates from a series of fact tables or individual transactions in the relational database. So, we might think that if we want to see the transactions that give a certain measure, we would look for them in the relational data warehouse. However, we can find these details right inside the SSAS model itself, and we can extract these details regardless of the relational engine. The mechanism that supports this is the drillthrough.

Drillthrough can either be issued as a standalone command, or it can be predefined as a cube-based action of that type. This recipe focuses on the first. It shows you how you can issue your own drillthrough command, whenever you need to analyze the data behind a certain cell. Having a predefined action is nice, but if you don't want to use a predefined action and want to test the drillthrough or simply customize it the way you need, all it takes is to create a DRILLTHROUGH type of MDX query and execute it in any tool that supports MDX queries, for example, the SQL Server Management Studio. Let's see how this can be done.

Getting ready

Start **SQL Server Management Studio** and connect to your SSAS 2016 instance. Click on the **New Query** button and check that the target database is **Adventure Works DW 2016**.

Suppose this is the pivot that we want to create:

	Actual	Budget	Forecast	Budget Variance	Budget Variance %
	Amount	Amount	Amount	Amount	Amount
Corporate	\$3,768,624.00	\$5,740,170.00	(null)	(\$1,971,546.00)	-34.35%
Corporate	(\$2,807,132.00)	(\$2,383,990.00)	(null)	(\$423,142.00)	17.75%
Executive General and Administration	(\$151,958.00)	(\$136,690.00)	(null)	(\$15,268.00)	11.17%
Inventory Management	(\$426,158.00)	(\$381,290.00)	(null)	(\$44,868.00)	11.77%
Manufacturing	(\$284,234.00)	(\$256,490.00)	(null)	(\$27,744.00)	10.82%
Quality Assurance	(\$172,364.00)	(\$147,770.00)	(null)	(\$24,594.00)	16.64%
Research and Development	\$7,735,915.00	\$9,142,770.00	(null)	(\$1,406,855.00)	-15.39%
Sales and Marketing	(\$125,445.00)	(\$96,370.00)	(null)	(\$29,075.00)	30.17%

The highlighted cell is the cell for which we want to get more detailed information. We want to see the data from the table rows that were evaluated to calculate the value of the selected cube cell.

The solution is to issue a drillthrough statement. Before we do so, let's see the MDX behind this pivot:

```

SELECT
    { [Scenario].[Scenario].[Scenario].ALLMEMBERS } *
    { [Measures].[Amount] } ON 0,
    { [Department].[Departments].MEMBERS } ON 1
FROM
    [Adventure Works]
WHERE
    ( [Date].[Calendar].[ Calendar Year ].&[2011] )
CELL PROPERTIES
    VALUE,
    FORMATTED_VALUE,
    FORE_COLOR,
    BACK_COLOR
  
```

The coordinates for the highlighted cell are Year = 2011, Scenario = Actual, Department = Research and Development, and Measure = Amount.

We cannot perform a DRILLTHROUGH command on a calculated member, which, in this case, is the budget variance scenario. Therefore, we're going to bypass that member in the coordinate and execute the drillthrough query using regular members only, in this case, the Actual member.

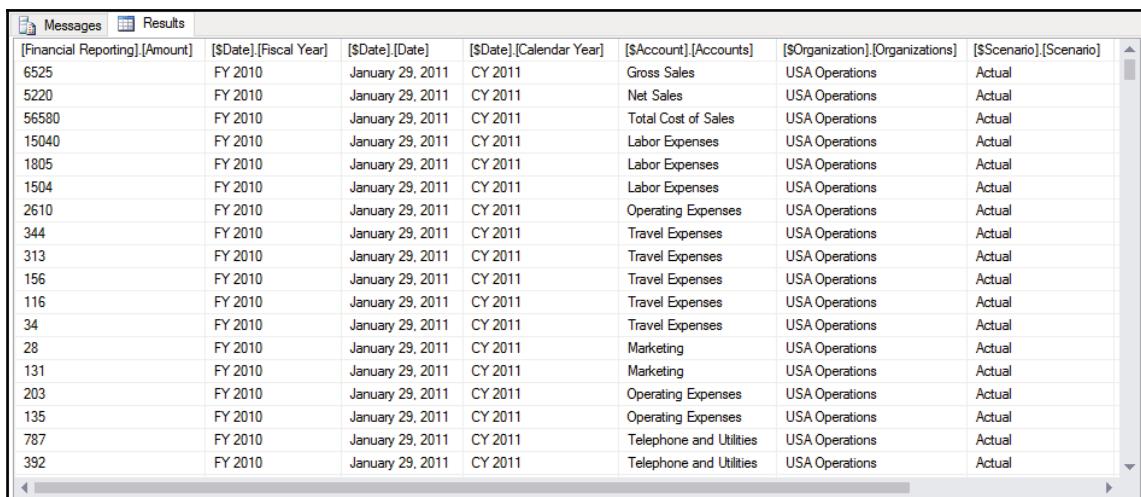

How to do it...

Follow these steps to execute a drillthrough query against a cube on an Analysis Services instance:

1. Execute the following MDX query:

```
DRILLTHROUGH
--MAXROWS 10
SELECT
FROM
    [Adventure Works]
WHERE
    ( [Date].[Calendar].[Calendar Year].&[2011],
      [Department].[Departments].&[6],
      [Scenario].[Scenario].&[1],
      [Measures].[Amount] )
```

2. The previous query returns all rows in the underlying **Financial Reporting** table. Notice the column names. They will be explained in the next section.

The screenshot shows the SSMS interface with the 'Results' tab selected. The results display a table with 20 rows and 8 columns. The columns are: [Financial Reporting].[Amount], [\$Date].[Fiscal Year], [\$Date].[Date], [\$Date].[Calendar Year], [\$Account].[Accounts], [\$Organization].[Organizations], and [\$Scenario].[Scenario]. The data includes various financial categories like Gross Sales, Net Sales, Total Cost of Sales, etc., across different dates and scenarios. The 'Actual' scenario is consistently selected for all rows.

[Financial Reporting].[Amount]	[\$Date].[Fiscal Year]	[\$Date].[Date]	[\$Date].[Calendar Year]	[\$Account].[Accounts]	[\$Organization].[Organizations]	[\$Scenario].[Scenario]
6525	FY 2010	January 29, 2011	CY 2011	Gross Sales	USA Operations	Actual
5220	FY 2010	January 29, 2011	CY 2011	Net Sales	USA Operations	Actual
56580	FY 2010	January 29, 2011	CY 2011	Total Cost of Sales	USA Operations	Actual
15040	FY 2010	January 29, 2011	CY 2011	Labor Expenses	USA Operations	Actual
1805	FY 2010	January 29, 2011	CY 2011	Labor Expenses	USA Operations	Actual
1504	FY 2010	January 29, 2011	CY 2011	Labor Expenses	USA Operations	Actual
2610	FY 2010	January 29, 2011	CY 2011	Operating Expenses	USA Operations	Actual
344	FY 2010	January 29, 2011	CY 2011	Travel Expenses	USA Operations	Actual
313	FY 2010	January 29, 2011	CY 2011	Travel Expenses	USA Operations	Actual
156	FY 2010	January 29, 2011	CY 2011	Travel Expenses	USA Operations	Actual
116	FY 2010	January 29, 2011	CY 2011	Travel Expenses	USA Operations	Actual
34	FY 2010	January 29, 2011	CY 2011	Travel Expenses	USA Operations	Actual
28	FY 2010	January 29, 2011	CY 2011	Marketing	USA Operations	Actual
131	FY 2010	January 29, 2011	CY 2011	Marketing	USA Operations	Actual
203	FY 2010	January 29, 2011	CY 2011	Operating Expenses	USA Operations	Actual
135	FY 2010	January 29, 2011	CY 2011	Operating Expenses	USA Operations	Actual
787	FY 2010	January 29, 2011	CY 2011	Telephone and Utilities	USA Operations	Actual
392	FY 2010	January 29, 2011	CY 2011	Telephone and Utilities	USA Operations	Actual

3. Notice the commented part of the query. Uncomment it and then run the query again. This time it returns only 10 rows, just like we've specified using the MAXROWS keyword.

How it works...

The DRILLTHROUGH command can be issued on a single cell only. That cell must not have calculated members or an error will occur.

We can limit the number of rows to be returned by this type of query using the MAXROWS keyword. In case we don't, the server-based setting OLAP \ Query \ DefaultDrillthroughMaxRows determines the limit. This setting is set to 10000 by default which is visible amongst the advanced settings of the server, where you can change it.

Column names tell us the origin of that column. Names starting with \$ denote a dimension table. Others can come from a single fact table (measure group) only. The simple form of a drillthrough query returns all measures in that fact table along with all the dimension keys. Besides the fact columns, all columns that represent the coordinate for the drillthrough are also returned.

The custom type of drillthrough query, the one that returns only the specified columns, is explained in the next section.

There's more...

It is possible to change the columns that a drillthrough command returns. This type of drillthrough is a custom drillthrough.

Using the RETURN keyword, we can specify which columns we want to get as the result of a drillthrough query. In addition to that, we can use nine functions dedicated to extract more metadata from the available columns. Here's an example to illustrate that:

```
DRILLTHROUGH
SELECT
FROM
    [Adventure Works]
WHERE
    ( [Date].[Calendar].[Calendar Year].&[2011],
      [Department].[Departments].&[6],
      [Scenario].[Scenario].&[1],
      [Measures].[Amount] )
RETURN
```

```
[$Date].[Date],  
MemberValue([$Date].[Date]),  
[$Organization].[Organizations],  
UnaryOperator([$Account].[Account]),  
[Financial Reporting].[Amount],  
[$Scenario].[Scenario],  
[$Department].[Department],  
[$Destination Currency].[Destination Currency Code],  
[$Account].[Accounts]
```

This query differs from the one in the previous section in several ways. First, it uses a specific set of columns to be returned. Next, it uses two functions: `MemberValue()` and `UnaryOperator()`.

The result of the query looks like this:

[\$Date].[Date]	[\$Date].[Date]	[\$Account].[Account]	[Financial Reporting].[Amount]	[\$Scenario].[Scenario]	[\$Department].[Department]	[\$Account].[Accounts]	[\$Account].[Account]
January 29, 2011	1/29/2011 12:00:00 AM	+	6525	Actual	Research and Development	Gross Sales	Intercompany Sales
January 29, 2011	1/29/2011 12:00:00 AM	-	5220	Actual	Research and Development	Net Sales	Returns and Adjustments
January 29, 2011	1/29/2011 12:00:00 AM	+	56580	Actual	Research and Development	Total Cost of Sales	Standard Cost of Sales
January 29, 2011	1/29/2011 12:00:00 AM	+	15040	Actual	Research and Development	Labor Expenses	Salaries
January 29, 2011	1/29/2011 12:00:00 AM	+	1805	Actual	Research and Development	Labor Expenses	Payroll Taxes
January 29, 2011	1/29/2011 12:00:00 AM	+	1504	Actual	Research and Development	Labor Expenses	Employee Benefits
January 29, 2011	1/29/2011 12:00:00 AM	+	2610	Actual	Research and Development	Operating Expenses	Commissions

The `UnaryOperator()` function returns the sign for the amount, the way it aggregates upwards. `MemberValue()` returns the date in the `datetime` format; normally, member names are strings (for example, the first column). Sometimes it's good to have original data types. This is how you do it.

You can also wrap the drillthrough query in the `OpenQuery` statement and use it in the relational environment. That way you can change the names it returns. However, there are some issues with duplicate names that `OpenQuery/OpenRowset` doesn't tolerate. Notice the first two columns in the previous screenshot. They both have the same column name, `[$Date]. [Date]`. The second column comes from the `MemberValue()` function, which preserved the data type. You will need to remove one of them. Another duplicate column is `[$Account]. [Account]`, one of which is returned by the `UnaryOperator()` function. Now you should choose between the unary operator and the value of the account.

Allowed functions and potential problems

The eight functions mentioned earlier can be found here:

<http://tinyurl.com/Drillthrough>.

For the reasons explained a moment ago, the use of the `DRILLTHROUGH` command is limited in distributed queries because of the issue with duplicate names in the relational environment.

More info

Drillthrough-related problems are covered in depth in the book *Expert Cube Development with SSAS Multidimensional Models*.

Other examples

The *Analysis Services Stored Procedure Project* assembly has an interesting drillthrough class that can bypass some of the restrictions imposed on the usage of the `DRILLTHROUGH` command. As mentioned earlier in this chapter, this assembly can be downloaded from here: <http://tinyurl.com/ASSPCodePlex>.
